Jeffrey P. Kharoufeh, and J. Cole Smith
Area Editors

A (45)

A Concise Overview of Applications of Ant Colony Optimization	1
A Review of Equity in Nonprofit and Public Sector: A Vehicle Routing Perspective	17
A Review of Tools, Practices, and Approaches for Sustainable Supply Chain Management	29
A Societal Cost of Obesity in Terms of Automobile Fuel Consumption	48
A Structural Clustering Algorithm for Large Networks	62
Accelerated Life Models	79
Accident Precursors and Warning Systems Management: A Bayesian Approach to Mathematical Models	88
Advanced Branching Processes	102
Age Replacement Policies	113
Aggregate Planning	119
Aggregation and Lumping of DTMCs	129
Aging, Characterization, and Stochastic Ordering	137
Air Traffic Management	144
Airline Resource Scheduling	156
Allocation Games	175
Alternating Renewal Processes	186
American Football: Rules and Research	189
An Introduction to Linear Programming	198
An Introduction to Platelet Inventory and Ordering Problems	215
An Introduction to Probabilistic Risk Analysis for Engineered Systems	222
An Introduction to R&D Portfolio Decision Analysis	248
An Overview of Inquiry-Based Learning in Mathematics	262
An Overview of Operations Research in Tennis	273
Analysis of Pairwise Comparison Matrices	290
Analytic Modeling of Insurgencies	299
Analytics in Retail	308
Ant Colony Optimization	319
Antithetic Variates	330
Application of Operations Research in Amusement Park Industry	337
Applying Value of Information and Real Options in R&D and New Product Development	345
Approximate Dynamic Programming I: Modeling	366
Approximate Dynamic Programming II: Algorithms	377
Approximation Algorithms for Stochastic Optimization Problems in Operations Management	392
Assessing Probability Distributions from Data	412
Assessing Remaining Useful Lifetime of Products	420

Association of European Operational Research Societies–434

Asymptotic Behavior of Continuous-Time Markov Chains–439

Asymptotic Behavior of Discrete-Time Markov Chains–444

Austrian Society of Operations Research (Oesterreichische Gesellschaft für Operations Research, Oegor)–451

Availability Analysis: Concepts and Methods–455

Availability in Stochastic Models–466

Average Reward of a Given MDP Policy–479

Aviation Safety and Security–482

Axiomatic Measures of Risk and Risk-Value Models–492

Axiomatic Models of Perceived Risk–503

B (28)

Backtrack Search Techniques and Heuristics–514

Backward and Forward Equations for Diffusion Processes–524

Basic CP Theory: Consistency and Propagation (Advanced)–529

Basic CP Theory: Search–540

Basic Interdiction Models–561

Basic Polyhedral Theory–569

Basis Reduction Methods–582

Batch Arrivals and Service-Single Station Queues–601

Batch Markovian Arrival Processes (BMAP)–608

Bayesian Aggregation of Experts' Forecasts–616

Bayesian Network Classifiers–630

Behavioral Economics and Game Theory–640

Behavioral Operations: Applications in Supply Chain Management–651

Benders Decomposition–663

Biclustering: Algorithms and Application in Data Mining–671

Bilevel Network Interdiction Models: Formulations and Solutions–677

Bilinear Optimization–688

Biosurveillance: Detecting, Tracking, and Mitigating the Effects of Natural Disease and Bioterrorism–695

Birth-and-Death Processes–712

Block Replacement Policies–718

Branch and Cut–725

Branch-and-Bound Algorithms–734

Branch-Price-and-Cut Algorithms–742

Branch-Width and Tangles–755

Brazilian Society of Operational Research–763

Brownian Motion and Queueing Applications–766
 Business Process Outsourcing–773
 Byelorussian Operational Research Society (ByORS)–781

C (62)

Calculating Real Option Values–784
 Call Center Management–799
 Campaign Analysis: An Introductory Review–807
 Capacity Allocation in Supply Chain Scheduling–816
 Capacity Allocation–825
 Capacity Planning in Health Care–834
 Capacity Planning–842
 Category and Inventory Management–851
 Central Path and Barrier Algorithms for Linear Optimization–870
 Chilean Institute of Operations Research–886
 Chinese Postman Problem–892
 Classic Financial Risk Measures–902
 Clique Relaxations–912
 Closed-Loop Supply Chains: Environmental Impact–919
 Clustering–930
 Cognitive Mapping and Strategic Options Development and Analysis (SODA)–942
 Coherent Systems–952
 Collaborative Procurement–960
 Column Generation–968
 Combinatorial Auctions: Complexity and Algorithms–982
 Combinatorial Auctions–994
 Combinatorial Traveling Salesman Problem Algorithms–1004
 Combining Exact Methods and Heuristics–1013
 Combining Forecasts–1022
 Combining Scenario Planning with Multiattribute Decision Making–1030
 Common Failure Distributions–1039
 Common Random Numbers–1050
 Communicating Decision Information to the Lay Risk Manager: A Consultant's Perspective–1061
 Comparisons of Risk Attitudes Across Individuals–1072
 Competing Risks and Limited Failure–1085
 Complementarity Problems–1097
 Computation and Dynamic Programming–1107

Computational Biology and Bioinformatics: Applications in Operations Research–1124

Computational Methods for CTMCs–1134

Computational Methods for DTMCs–1141

Computational Pool: An OR-Optimization Point of View–1153

Concepts of Network Reliability–1165

Conceptual Modeling for Simulation–1176

Condition-Based Maintenance Under Markovian Deterioration–1188

Conic Optimization Software–1200

Conservation Laws and Related Applications–1210

Constraint Programming Links with Math Programming–1223

Constraint Qualifications–1238

Continuous Optimization by Variable Neighborhood Search–1247

Continuous-Time Control under Stochastic Uncertainty–1260

Continuous-Time Martingales–1287

Contributions to Software Reliability with OR Applications–1291

Control Variates–1310

Cooperative Game Theory with Nontransferable Utility–1319

Cooperative Games with Transferable Utility–1327

Coordination of Production and Delivery in Supply Chain Scheduling–1343

Cost-Effectiveness Analysis, Health-Care Policy, and Operations Research Models–1354

Cover Inequalities–1370

Credit Risk Assessment–1376

Credit Risk–1383

Croatian Operational Research Society–1393

Cross-Entropy Method–1396

CTMCs with Costs and Rewards–1403

Customer Relationship Management: Maximizing Customer Lifetime Value–1408

Customized Price Responses to Bid Opportunities in Competitive Markets–1419

Cusum Charts for Multivariate Monitoring and Forecasting–1428

Czech Society for Operations Research–1435

D (50)

Damage, Stress, Degradation, Shock–1437

Dantzig-Wolfe Decomposition–1444

Data Classification and Prediction–1456

Data Mining in Construction Bidding Policy–1462

Decision Analysis and Counterterrorism–1472

Decision Making Under Pressure and Constraints: Bounded Rationality–1480

Decision Making with Partial Probabilistic or Preference Information–1488

Decision Problems and Applications of Operations Research at Marine Container Terminals–1497

Decision Rule Preference Model–1517

Decision-Theoretic Foundations of Simulation Optimization–1533

Decomposition Algorithms for Two-Stage Recourse Problems–1543

Decomposition Methods for Integer Programming–1553

Defining Objectives and Criteria for Decision Problems–1564

Definition and Examples of Continuous-Time Markov Chains–1575

Definition and Examples of DTMCs–1579

Definition and Examples of Renewal Processes–1585

Degeneracy And Variable Entering/Exiting Rules–1589

Delayed Renewal Processes–1596

Demand Responsive Transportation–1599

Describing Decision Problems by Decision Trees–1608

Description of the French Operational Research and Decision-Aid Society: Société Française de Recherche Opérationnelle et d'aide À la Décision (ROADEF)–1625

Descriptive Models of Decision Making–1629

Descriptive Models of Perceived Risk–1645

Design and Control Principles of Flexible Workforce in Manufacturing Systems–1654

Design Considerations for Supply Chain Tracking Systems–1671

Design for Manufacturing and Assembly–1681

Design for Network Resiliency–1711

Deterministic Dynamic Programming (DP) Models–1728

Deterministic Global Optimization–1736

Different Formats for the Communication of Risks: Verbal, Numerical, and Graphical Formats–1756

Differential Games–1767

Direct Search Methods–1775

Discrete Optimization with Noisy Objective Function Measurements–1788

Discrete-Time Martingales–1802

Discretization Methods for Continuous Probability Distributions–1805

Disjunctive Inequalities: Applications and Extensions–1818

Disjunctive Programming–1828

Distributed Simulation in ORMS–1837

Domination Problems–1850

Drama Theory–1868

DTMCS with Costs and Rewards–1877

Dual Simplex–1882

Dynamic Auctions–1892

Dynamic Models for Robust Optimization–1903

Dynamic Pricing Strategies for Multiproduct Revenue Management Problems–1914

Dynamic Pricing Under Consumer Reference-Price Effects–1927

Dynamic Programming: Introductory Concepts–1944

Dynamic Programming Via Linear Programming–1955

Dynamic Programming, Control, and Computation–1961

Dynamic Vehicle Routing–1967

E (22)

Edgeworth Market Games: Price-Taking and Efficiency–1978

Effective Application of GRASP–1992

Effective Application of Guided Local Search–2001

Effective Application of Simulated Annealing–2012

Efficient Iterative Combinatorial Auctions–2022

Efficient Use of Materials and Energy–2036

Electronic Negotiation Systems–2042

Eliciting Subjective Probabilities from Individuals and Reducing Biases–2050

Eliciting Subjective Probability Distributions from Groups–2063

Ellipsoidal Algorithms–2070

Emergency Medical Service Systems that Improve Patient Survivability–2083

Estimating Failure Rates and Hazard Functions–2098

Estimating Intensity and Mean Value Function–2114

Estimating Survival Probability–2128

Estonian Operational Research Society–2144

Eulerian Path and Tour Problems–2147

Evacuation Planning–2154

Evaluating and Comparing Forecasting Models–2165

Evaluations of Single- and Repeated-Play Gambles–2176

Evolutionary Algorithms–2183

Evolutionary Game Theory and Evolutionary Stability–2196

Exact Solution of the Capacitated Vehicle Routing Problem–2207

F (18)

Fairness and Equity in Societal Decision Analysis–2219

Fast and Frugal Heuristics–2228

Feasible Direction Method–2236

Feature Extraction and Feature Selection: A Survey of Methods in Industrial Applications–2243

Fictitious Play Algorithm–2254

Finite Population Models-Single Station Queues–2262

Fire Department Deployment and Service Analysis–2268

Fluid Models of Queueing Networks–2277

Forecasting Approaches for the High-Tech Industry–2292

Forecasting for Inventory Planning under Correlated Demand–2298

Forecasting Nonstationary Processes–2309

Forecasting: State-Space Models and Kalman Filter Estimation–2320

Formulating Good MILP Models–2329

Foundations of Constrained Optimization–2343

Foundations of Decision Theory–2353

A CONCISE OVERVIEW OF APPLICATIONS OF ANT COLONY OPTIMIZATION

THOMAS STÜTZLE
MANUEL LÓPEZ-IBÁÑEZ
MARCO DORIGO
IRIDIA, CoDE, Université Libre de
Bruxelles (ULB), Brussels,
Belgium

Ant colony optimization (ACO) [1–3] is a metaheuristic for solving hard combinatorial optimization problems inspired by the indirect communication of real ants. In ACO algorithms, (artificial) ants construct candidate solutions to the problem being tackled, making decisions that are stochastically biased by numerical information based on (artificial) pheromone trails and available heuristic information. The pheromone trails are updated during algorithm execution to bias the ants search toward promising decisions previously found. The article titled *Ant Colony Optimization* gives a detailed overview of the main concepts of ACO.

Despite being one of the youngest metaheuristics, the number of applications of ACO algorithms is very large. In principle, ACO can be applied to any combinatorial optimization problem for which some iterative solution construction mechanism can be conceived. Most applications of ACO deal with $\mathcal{NP}$ -hard combinatorial optimization problems, that is, with problems for which no polynomial time algorithms are known. ACO algorithms have also been extended to handle problems with multiple objectives, stochastic data, and dynamically changing problem information. There are extensions of the ACO metaheuristic for dealing with problems with continuous decision variables, as well.

This article provides a concise overview of several noteworthy applications of ACO algorithms. This overview is necessarily incomplete because the number of currently available ACO applications goes into the hundreds. Our description of the applications

follows the classification used in the 2004 book on ACO by Dorigo and Stützle [3] but extending the list there with many recent examples. Tables 1 and 2 summarize these applications.

APPLICATIONS TO $\mathcal{NP}$ -HARD PROBLEMS

ACO was primarily intended for solving combinatorial optimization problems, among which $\mathcal{NP}$ -hard problems are the most challenging ones. In fact, no polynomial-time algorithms are known for such problems, and therefore heuristic techniques such as ACO are often used for generating high-quality solutions in reasonable computation times.

Routing Problems

Routing problems involve one or more agents visiting a predefined set of locations, and the objective function and constraints depend on the order in which the locations are visited. Perhaps the best-known example is the traveling salesman problem (TSP) [104,105]. In fact, the first ACO algorithm, ant system (AS) [4,5,106,107], was first tested using this problem. Although AS could not compete with state-of-the-art algorithms for the TSP, it was the starting point for the development of various high performing ACO algorithms. The application of AS to the TSP also stimulated the application of ACO to other routing and combinatorial problems.

For instance, ACO has obtained very good results for the sequential ordering problem, an extension of asymmetric TSP with precedence constraints among nodes. At the time it was proposed by Gambardella and Dorigo [18], the algorithm was the best available algorithm for this problem, improving upon many best-known solutions. Recently, stochastic sampling has been integrated into a Beam-ACO algorithm for the TSP with time windows [19], which is an extension of the classical TSP with time window constraints; Beam-ACO is a combination of ACO algorithms with beam-search [32].

ACO algorithms have been successful in tackling various variants of the vehicle routing problem (VRP). The first application of ACO to the capacitated VRP (CVRP) was

due to Bullnheimer *et al.* [9]. More recently, Reimann *et al.* [10] proposed a particular ACO algorithm (D-Ants) for the capacitated VRP. Gambardella *et al.* [12] introduced

MACS-VRPTW, an ACO algorithm for the VRP with time window (VRPTW) constraints, which reached state-of-the-art results when it was proposed. Favaretto *et al.* [13] proposed an ACS algorithm for a variant of the VRP with multiple time windows and multiple visits (VRPMTWMV). Fullerer *et al.* [15] used an ACO algorithm for a problem that combines the two-dimensional packing and the capacitated vehicle routing problem, showing that it outperforms a tabu search (TS) algorithm. In this problem, items of different sizes and weights are loaded in vehicles with a limited weight capacity and limited two-dimensional loading surface, and then they are distributed to the customers. Other variants of VRP with different loading constraints have also been tackled by means of ACO [14,16].

Ke *et al.* [17] have recently proposed an ACO approach to the team orienteering problem (TOP), where the goal is to find the set of paths from a starting point to an ending point that maximizes the reward obtained by visiting certain locations taking into account that there are restrictions on the length of each path.

Scheduling Problems

Scheduling problems concern the assignment of jobs to one or various machines over time. Input data for these problems are processing times but also often additional setup times, release dates and due dates of jobs, measures for the jobs' importance, and precedence constraints among jobs. Scheduling problems have been an important application area of ACO algorithms, and the currently available ACO applications in scheduling deal with many different job and machine characteristics.

The single-machine total weighted tardiness problem (SMTWTP) has been tackled by both den Besten *et al.* [20] and Merkle and Middendorf [21,22] using variants of ACS (ACS-SMTWTP). In ACS-SMTWTP, a solution is determined by a sequence of jobs. The positions of the sequence are filled in their canonical order, that is, first a job is assigned to position 1, next a job to position 2, and so on, until position n . Pheromone trails

are defined as the desirability of scheduling job j at position i , a pheromone trail definition that is used in many ACO applications to scheduling problems [20,26,108,109]. Merkle and Middendorf [21] used sophisticated heuristic information and an algorithmic technique called *pheromone summation rule*, which has proven to be useful in many applications of ACO to scheduling problems. On the other hand, den Besten *et al.* [20] combined ACS-SMTWTP with a powerful local search algorithm, resulting in one of the best algorithms available for this problem in terms of solution quality. Another application of ACO to a variant of this problem with sequence-dependent setup times has recently been studied by Liao and Juan [24]. Meyer and Ernst [23] and Meyer [25] studied the integration of constraint programming techniques into ACO algorithms using a single-machine problem with sequence-dependent setup times, release dates, and deadlines for jobs, as a case study.

ACO algorithms have also been proposed for the permutation flow-shop problem (FSP). The first approach is due to Stützle [26], who proposed a hybrid between $\mathcal{MMAS}$ and ACS. Later, Rajendran and Ziegler [27] improved its performance by introducing the pheromone summation rule. For this problem, however, the results of existing ACO algorithms are behind the current state-of-the-art algorithms. This is also the case for the well-known job-shop problem [30], although recent results hybridizing ACO and TS seem promising [31]. Nevertheless, for various other scheduling problems ACO algorithms are among the best performing algorithms available nowadays. Beam-ACO, the hybrid between beam search and ACO, is a state-of-the-art algorithm for open shop scheduling [32]. In addition, a variant of $\mathcal{MMAS}$ obtained excellent results in the group shop problem [30].

Another scheduling problem where ACO obtained excellent results is the resource-constrained project scheduling problem, in which a set of activities must be scheduled, subject to resource constraints and precedence constraints among the activities, such that the last activity is completed as early as possible. At the time of its publication, the

ACO algorithm proposed by Merkle *et al.* [29] was the best available.

Finally, state-of-the-art results have been obtained in the car sequencing problem by the ACO algorithm proposed by Solnon [34], and these results have been further improved by Morin *et al.* [35] by means of a specialized pheromone model. The car sequencing problem has also been used as an example application by Khichane *et al.* [33] to explore the integration of constraint programming techniques into ACO algorithms.

Subset Problems

The goal in subset problems is, generally speaking, to find a subset of the available items that minimizes a cost function defined over the items and that satisfies a number of constraints. This is a wide definition that can include other classes of problems. There are, however, two characteristic properties of the solutions to subset problems: The order of the solution components is irrelevant, and the number of components of a solution may differ from solution to solution.

An important subset problem is the set covering problem (SCP). Lessing *et al.* [41] compared the performance of a number of ACO algorithms for the SCP, with and without the usage of a local search algorithm based on 3-flip neighborhoods [110]. The best performance results were obtained, as expected, when including local search. For a large number of instances, the computational results were competitive with state-of-the-art algorithms for the SCP.

Leguizamón and Michalewicz [36] proposed the first ACO applications to the multiple knapsack and to the maximum independent set problems, which were, however, not competitive with the state-of-the-art. Currently, the best performing ACO algorithm for the multiple knapsack problem is due to Ke *et al.* [37]. Levine and Ducatelle [40] adapted $\mathcal{MMAS}$ to the well-known bin-packing problem and compared its performance with the hybrid grouping genetic algorithm [111], and with Martello and Toth's reduction method [112]. The $\mathcal{MMAS}$ algorithm outperformed both, obtaining better solutions in a much shorter time. Solnon and Fener [45] carried out a comprehensive

study for the maximum clique problem. Their conclusion was that ACO combined with appropriate local search can match the quality of state-of-the-art heuristics. Blesa and Blum [49] applied ACO to the problem of finding edge-disjoint paths in networks, and found the performance of the proposed ACO superior in terms of both solution quality and computation time when compared with a multistart greedy algorithm. Another interesting application is the work of Sivagaminathan and Ramakrishnan [50], which discusses how ACO may be hybridized with neural networks for optimizing feature selection in multivariate analysis.

Cordone and Maffioli [39] introduced the weight constrained graph tree partition problem, and tested different variants of ACS with and without local search. Blum and Blesa [43] tackled the edge-weighted k -cardinality tree problem (or k -minimum spanning tree), where the goal is to find a tree over a graph with exactly k edges minimizing the sum of the weights. They compared a $\mathcal{MMAS}$ variant, TS, and an evolutionary algorithm. Their results showed that none of the approaches was superior to the others in all instance classes tested, and that $\mathcal{MMAS}$ was better suited for instances where the value of k was much smaller than the number of vertices.

A subset problem closely related to the CVRP is the capacitated minimum spanning tree problem, which has been effectively tackled by a hybrid ACO algorithm [44] based on a previous ACO algorithm for the CVRP [10]. More recently, Hernández and Blum [51] considered the minimization of power consumption when multicasting in static wireless ad-hoc networks. This problem can be stated as an $\mathcal{NP}$ -hard combinatorial problem, where the goal is to find a directed tree over the network of nodes. Their proposed ACO algorithm outperforms existing algorithms for several variants of this problem.

Finally, a class of problems for which ACO has recently shown competitive results is that of multilevel lot-sizing with [46,48] and without capacity constraints [47]. In these problems, a subset of items is scheduled for production at each time interval, and the goal is to minimize the cost of producing the items,

taking into account several constraints and relations between the items.

Assignment and Layout Problems

In assignment problems, a set of items has to be assigned to a given number of resources subject to some constraints. Probably, the most widely studied example is the quadratic assignment problem (QAP), which was among the first problems tackled by ACO algorithms [5,52,53]. Various high-performing ACO algorithms for the QAP have followed this initial work. Among them is the approximate nondeterministic tree search (ANTS) algorithm by Maniezzo [113] a combination of ACO with tree search techniques involving the usage of lower bounds to rate solution components and to prune extensions of partial solutions. The computational results of ANTS on the QAP were very promising. Another high-performing ACO algorithm is the *MAX-MIN* ant system (*MMAS*) proposed by Stützle and Hoos [8], which is among the best algorithms available for large, structured instances of the QAP.

The ANTS algorithm has also been applied to the frequency assignment problem (FAP), in which frequencies have to be assigned to links and there are constraints on the minimum distance between the frequencies assigned to each pair of links. ANTS showed good performance on some classes of FAP instances in comparison with other approaches [56]. Other applications of ACO to assignment problems include university course timetabling [59,60] and graph coloring [54]. The work of Solnon [57,58] applies ACO algorithms to the general class of constraint satisfaction problems (CSPs); in fact, decision variants of problems such as graph coloring and frequency assignment can be seen as cases of CSPs. Within this class, Pinto *et al.* [62] studied the application of ACO to regular and dynamic MAX-SAT problems.

Another notable example is the generalized assignment problem, where a set of tasks have to be assigned to a set of agents with a limited total capacity, minimizing the total assignment cost of tasks to agents. The *MMAS* algorithm proposed by Lourenço and

Serra [55] was, at the time of its publication, close to the state-of-the-art algorithm for this problem. More recently, Doerner *et al.* [61] tackled a real-world problem related to ambulance locations in Austria by means of an ACO algorithm; and Blum [64] has shown that the hybrid between beam search and ACO, Beam-ACO, is a state-of-the-art algorithm for simple assembly line balancing. In the section titled “Industrial Applications,” we mention an industrial application of ACO to assembly line balancing. Finally, Silva *et al.* [65] have used ACO for a complex supply chain management problem that combines aspects of the generalized assignment, scheduling, and vehicle routing problems.

Machine Learning Problems

Diverse problems in the field of machine learning have been tackled by means of ACO algorithms. Notable examples are the work of Parpinelli *et al.* [69] and Martens *et al.* [70] on applying ACO to the problem of learning classification rules. This work was later extended by Otero *et al.* [71] in order to handle continuous attributes. De Campos *et al.* [66,67] adapted Ant Colony System for the problem of learning the structure of Bayesian networks, and Pinto *et al.* [68] have recently extended this work. Finally, the work of Socha and Blum [89] for training neural networks by means of ACO is also an example of the application of ACO algorithms to continuous problems.

Bioinformatics Problems

Computer applications to molecular biology (bioinformatics) have originated many $\mathcal{NP}$ -hard combinatorial optimization problems. We include in this section general problems that have attracted considerable interest due to their applications to bioinformatics. This is the case of the shortest common super-sequence problem (SCSP), which is a well-known $\mathcal{NP}$ -hard problem with applications in DNA analysis. Michel and Middendorf [72,73] proposed an ACO algorithm for the SCSP, obtaining state-of-the-art results, in particular, for structured instances that are typically found in real-world applications.

An important problem in bioinformatics is protein folding, that is, the prediction of a protein's structure based on its sequence of amino acids. A simplified model for protein folding is the two-dimensional hydrophobic-polar protein folding problem [114]. Shmygelska and Hoos [74] have successfully applied ACO to this problem and its three-dimensional variant. The performance of the resulting ACO algorithm is comparable to the best existing specialized algorithms for these problems.

Interesting is also the work of Blum *et al.* [78], where they propose a *multilevel framework* based on ACO for the problem of DNA sequencing by hybridization. An earlier proposal of multilevel ACO frameworks is due to Korošec *et al.* [115]. Multilevel techniques [116,117] solve a hierarchy of successively smaller versions of the original problem instance. The solutions obtained at the lowest level of the hierarchy are transformed into solutions for the next higher level, and improved by an optimization algorithm, such as an ACO algorithm.

Other problems in bioinformatics have been successfully tackled by means of ACO algorithms: Korb *et al.* [75,76] considered the flexible protein–ligand docking problem, for which the proposed ACO algorithm reaches state-of-the-art performance, and Benedettini *et al.* [79] recently studied the problem of haplotype inference under pure parsimony. ACO algorithms are sometimes hybridized with Machine Learning techniques. An example is the recent work of Ressom *et al.* [77] on a selection problem in biomarker identification, which combines ACO with support vector machines.

APPLICATIONS TO PROBLEMS WITH NONSTANDARD FEATURES

We review in this section applications of ACO algorithms to problems having additional characteristics such as multiple objective functions, time-varying data, and stochastic information about objective values or constraints. In addition, we mention applications of ACO to network routing and continuous optimization problems.

Multiobjective Optimization

In many real-world problems, candidate solutions are evaluated according to multiple, often conflicting objectives. Sometimes the importance of each objective can be exactly weighted, and hence objectives can be combined into a single scalar value by using, for example, a weighted sum. This is the approach used by Doerner *et al.* [118] for a biobjective transportation problem. In other cases, objectives can be ordered by their relative importance in a lexicographical manner. Gambardella *et al.* [12] proposed a two-colony ACS algorithm for the vehicle routing problem with time windows, where the first colony improves the primary objective and the second colony tries to improve the secondary objective while not worsening the primary one.

When there is no *a priori* knowledge about the relative importance of objectives, the goal usually becomes to approximate the set of Pareto-optimal solutions—a solution is Pareto optimal if no other solution is better or equal for all objectives and strictly better in at least one objective. Iredi *et al.* [80] were among the first to discuss various alternatives for extending ACO to multiobjective problems in terms of Pareto-optimality. They also tested a few of the proposed variants on a biobjective scheduling problem. Another early work is the application of ACO to multiobjective portfolio problems by Doerner *et al.* [81,82]. Later studies have proposed and tested various combinations of alternative ACO algorithms for multiobjective variants of the QAP [83,84], the knapsack problem [85], activity crashing [87], and the biobjective orienteering problem [88]. García-Martínez *et al.* [86] reviewed existing multiobjective ACO algorithms and carried out an experimental evaluation of several ACO variants using the bicriteria TSP as a case study. Angus and Woodward [119] give another detailed overview of available multiobjective ACO algorithms.

Stochastic Optimization Problems

In stochastic optimization problems, data are not known exactly before generating a solution. Rather, because of uncertainty,

noise, approximation, or other factors, what is available is stochastic information on the objective function value(s), on the decision variable values, or on the constraint boundaries.

The first application of ACO algorithms to stochastic problems was to the probabilistic TSP (PTSP). In the PTSP, each city has associated a probability of requiring a visit, and the goal is to find an *a priori* tour of minimal expected length over all cities. Bianchi *et al.* [91] and Bianchi and Gambardella [92] proposed an adaptation of ACS for the PTSP. Very recently, this algorithm was improved by Balaprakash *et al.* [93], resulting in a state-of-the-art algorithm for the PTSP. Other applications of ACO to stochastic problems include vehicle routing problems with uncertain demands [94], and the selection of optimal screening policies for diabetic retinopathy [95]. The latter approach builds on the S-ACO algorithm proposed earlier by Gutjahr [120].

Dynamic Optimization Problems

Dynamic optimization problems are those whose characteristics change while being solved. ACO algorithms have been applied to such versions of classical $\mathcal{NP}$ -hard problems. Notable examples are applications to dynamic versions of the TSP, where the distances between cities may change or where cities may appear or disappear [98–101]. More recently, Montemanni *et al.* [102] and Donati *et al.* [103] discuss applications of ACS to dynamic vehicle routing problems, reporting good results on both artificial and real-world instances of the problem. Other notable examples of dynamic problems are routing problems in communication networks, which are discussed in the following section.

Communication Network Problems

Some system properties in telecommunication networks, such as the availability of links or the cost of traversing links, are time-varying. The application of ACO algorithms to routing problems in such networks is among the main success stories in ACO. One of the first applications by Schoonderwoerd *et al.* [121] concerned routing in

circuit-switched networks, such as classical telephone networks. The proposed algorithm, called *ABC*, was demonstrated on a simulated version of the British Telecom network.

A very successful application of ACO to dynamic network routing is the AntNet algorithm, proposed by Di Caro and Dorigo [96,122]. AntNet was applied to routing in packet-switched networks, such as the Internet. Experimental studies compared AntNet with many state-of-the-art algorithms on a large set of benchmark problems under a variety of traffic conditions [96]. AntNet proved to be very robust against varying traffic conditions and parameter settings, and it always outperformed competing approaches.

Several other routing algorithms based on ACO have been proposed for a variety of wired network scenarios [123,124]. More recent applications of these strategies deal with the challenging class of mobile ad hoc networks (MANETs). Because of the specific characteristics of MANETs (very high dynamics and link asymmetry), the straightforward application of the ACO algorithms developed for wired networks has proven unsuccessful [125]. Nonetheless, an extension of AntNet that is competitive with state-of-the-art routing algorithms for MANETs has been proposed by Ducatelle *et al.* [97, 126]. For recent, in-depth reviews of applications of ACO to dynamic network routing problems, we refer to Refs 127 and 128.

Continuous Optimization Problems

Continuous optimization problems arise in a large number of engineering applications. Their main difference from combinatorial problems, which were the exclusive application field of ACO in the early research efforts, is that decision variables in such problems have a continuous, real-valued domain. Recently, various proposals have been made on how to handle continuous decision variables within the ACO framework [129–131]. In the continuous ACO algorithm proposed by Socha and Dorigo [90], probability density functions, explicitly represented by Gaussian kernel functions, correspond to the pheromone models. Extensions of this approach also exist for mixed-variable—continuous

and discrete—problems [132]. A notable application of ACO algorithms for continuous optimization is the training of feed-forward neural networks [89]. Interestingly, there exist also successful applications of ACO to continuous problems that discretize the real-valued domain of the variables. An example is the PLANTS algorithm for the protein–ligand docking problem [76], which combines a discrete ACO algorithm with a local search that works on the continuous domain of the variables.

Industrial Applications

While most research is done on academic applications, commercial companies have started to use ACO algorithms for real-world applications [11]. The company AntOptima (www.antoptima.com) develops and markets ACO-based solution methods for tackling industrial vehicle routing problems. Features common to real-world applications are time-varying data, multiple objectives, or the availability of stochastic information about events or data. Moreover, engineering problems often do not have a mathematical formulation in the traditional sense. Rather, algorithms have to rely on an external *simulator* to evaluate the quality and feasibility of candidate solutions. Examples of applications of ACO relying on simulation are the design [133] and operation [134] of water distribution networks. Other interesting real-world applications are those of Gravel, Price and Gagné [28], who applied ACO to an industrial scheduling problem in an aluminum casting center, and those of Bautista and Pereira [63,135,136], who successfully applied ACO to solve an assembly line balancing problem for a bike line assembly.

CONCLUSIONS

Nowadays, ACO is a well-established metaheuristic applied to a wide range of optimization problems and with hundreds of successful implementations. Several of these implementations have shown to be, at least at the time of their publication, the state-of-the-art for the respective problems tackled,

including problems such as vehicle routing, sequential ordering, quadratic assignment, assembly line balancing, open-shop scheduling, and various others. Applications of ACO to dynamic routing problems in telecommunication networks have been particularly successful, probably because several algorithm characteristics match well with the features of the applications.

By analyzing the many available ACO implementations, one can identify ingredients necessary for the successful application of ACO. Firstly, an effective mechanism for iteratively constructing solutions must be available. Ideally, this construction mechanism exploits problem-specific knowledge by using appropriate heuristic information. Secondly, the best performing ACO algorithms have specialized features that allow to carefully control the balance between the exploration of new solutions and the intensification of the search around the best solutions. Such control mechanisms are offered by advanced ACO algorithms such as ACS or MMAS. In fact, the original AC has been abandoned by now in favor of better performing variants. Thirdly, the usage of local search algorithms for improving the solutions constructed by the ants is very successful in practice. Finally, the integration of other techniques such as constraint programming, tree search techniques, or multilevel frameworks often yields a further improvement in performance or increases the robustness of the algorithms.

Further information on ACO and related topics can be obtained by subscribing to the moderated mailing list *aco-list*, and by visiting the ACO web page (www.aco-metaheuristic.org).

Public, nonprofit, and commercial sector organizations differ from each other in many aspects including goals, activities, and stakeholders. The differences among these sectors have been the subject of research in various disciplines. In operations research (OR), public sector is mainly characterized by nonmonetary performance requirements, multiple constituencies, and public scrutiny on decisions [1].

In this article, *public service* refers to services provided to the society by public and/or nonprofit sector organizations. Although some public services such as library, emergency, and postal services are primarily provided by government agencies, there are numerous public services, including material and housing assistance, disaster relief, various health and social services that are also provided by nonprofit sector organizations, such as food banks, housing associations, and nursing homes. Indeed, nonprofit organizations play a large and increasing role in delivering services traditionally provided by governments. In some cases, nonprofit and government agencies work in partnership complementing each other in providing public services. While nonprofit organizations provide greater service flexibility and access to underserved regions and populations, governments can ensure larger coverage with more resources. In this article, we focus on a common concern of both public and nonprofit organizations: achieving high performance in delivering public service.

The fundamental differences in goals between public/nonprofit and private sector organizations lead to unique performance metrics for each sector. The most common types of metrics in OR are *effectiveness* and *efficiency*. Effectiveness assesses the extent to which organizations attain their goals, whereas efficiency measures the amount of resources used to achieve specified goals [2,3]. For instance, for a private sector organization, effectiveness can be measured in terms of increased sales and improved customer service quality, and efficiency can be assessed by measured inputs (costs, resources) used to achieve these goals. For public and nonprofit organizations, providing equal access is an important component of their strategic goals and missions. Indeed, *equity* is a distinguishing aspect of decision making in the nonprofit and public sectors in addition to traditional effectiveness and efficiency objectives.

Concepts such as equity, fairness, and justice are subject to broad interpretation and endless debate, as discussed in Ref. 4. These concepts have been interpreted and practiced in many context-dependent ways. As such, equity and fairness may have distinct meanings in different OR applications in the literature; for instance, airspace allocation in airline traffic management; bandwidth allocation in telecommunications; cost/benefit allocation in collaborative logistics; or organ, blood, and drug allocation in health care. While there are various OR applications for which equity is pertinent, this article focuses on equity issues in public and nonprofit sector applications. Since public and nonprofit organizations typically operate with limited resources, defining equity is closely related to determining equity principles for allocating those resources. The complexities associated with allocating resources in public and nonprofit sectors can be related to value judgments made in defining equity in a particular context; that is, *fairness based on what, who should benefit, and how is fairness measured?*

Equity-related issues in the public/non-profit sector have been widely studied using OR models primarily in few areas, such as *facility location*, while some other areas such as *vehicle routing* have received relatively less attention. There is a large body of literature in facility location both in terms of public sector applications (such as locating undesirable/controversial public facilities, emergency service facilities, and public housing) and the types of equity metrics used (see Refs 4, 5 for reviews). In locating such public service facilities, it is generally assumed that either users travel to the facility, or in some cases, such as in ambulance location, the resources positioned in the facilities travel to users. Therefore, providing equal access is usually defined based on the distance between facilities and the users. However, in some services provided by public and nonprofit organizations, demands for services and goods occur at spatially distributed locations and must be satisfied by visiting each user sequentially using the available logistical resources. Therefore, *vehicle routing* is another important problem faced by public and nonprofit decision makers. Although routing-related decisions such as sequence of visits and delivery amounts may affect equitable service provision, we observe that most of the vehicle routing literature focuses on the traditional efficiency (cost-based) objectives and equity is not well studied. In this article, we focus on equity issues within the context of vehicle routing and provide examples from public and nonprofit sector applications for which equity is a key performance indicator. Although we focus only on equity in the context of vehicle routing, this article also sheds light on how OR can be used to model equity in other contexts.

The remainder of this article is organized as follows. In section titled “Equity Overview,” we provide a broad overview of equity characterization and measurement. In section titled “Equity in Routing,” we focus on equity in vehicle routing and review the characteristics of various OR applications that consider equity. Section titled “Conclusion and Future Research” summarizes and identifies future research areas.

EQUITY OVERVIEW

There is no universal definition for equity. In general, equity is conceptually related to fairness, justice, and impartiality and considered in association with allocation of resources, benefits, or disbenefits. Many disciplines including economics, philosophy, political science, and mathematics have studied equity and equitable resource allocation. In this section, we provide a broad overview of how equity is approached in OR.

Equity is not new to OR; indeed, there is a diverse body of literature that addresses equity-related issues, from studies that describe the aspects of equity measurement through a discussion of different equity principles and metrics to papers that analyze the mathematical properties of existing or newly proposed equity objectives/metrics. Relatively few studies study the implications of using different equity metrics and the trade-offs between equity and other relevant objectives such as efficiency when incorporating equity in models.

Studying equity involves three interrelated steps: (i) definition of equity elements, (ii) policy design and implementation, and (iii) measurement of the outcomes of the policies, shown in Fig. 1.

Definition

Defining equity may not be straightforward since it often requires judgments regarding how individuals are affected by critical decisions; for example, allocating emergency relief resources, routing of hazardous waste. In general, a decision is deemed equitable when its effects are approximately equal across the affected parties. Therefore, defining equity requires characterizing three elements: *equity determinant*, *affected parties*, and their relevant *attributes*.

To characterize the effects, one must determine a basis for equity comparison (i.e., fairness based on what?), which Marsh and Schilling define as the *equity determinant*. Then, *the affected parties* addressed in the comparison (i.e., fairness among whom?) and their relevant *attributes* (i.e., population, demand, social needs) must be identified. As described in Ref. 4, an affected party can refer

Figure 1. Equity characterization and measurement.

to a single individual or groups of individuals defined based on geographical, demographic, physical, and temporal aspects.

Equity determinants and affected parties capture the characteristics of the applications. For instance, in queueing systems, a typical equity determinant is service waiting time and can be compared among individuals. In resource allocation, an equity determinant can be the amount of commodities allocated among spatially distributed groups of individuals. In a workload allocation problem, an equity determinant can be the time required to complete tasks, measured across individual employees. In facility location, equity determinants are typically defined based on distance or time. For instance, in locating a desirable public facility such as a fire station, affected individuals can be grouped geographically and the effects can be characterized based on the distance or response time between the facility and the groups of beneficiaries.

Policy

In the next interrelated step, policies are designed and implemented with the above equity elements in mind; that is, equity determinants, affected parties, and critical attributes of the affected parties. Therefore, how one defines equity and fairness directly affects the types of policies to be designed and implemented. For instance, in queueing systems such as banks, policies based on first-come, first-served or first-in, first-out are traditionally considered the most fair. However, depending on how equity is characterized, policies that prioritize based on service times or urgency can also be considered to be fair. In public service provision, alternative policies may exist to allocate public resources equitably. In Ref. 3, the author discusses examples of an allocation policy based on equal inputs that may result in imbalanced outputs; for example, assigning an equal number of ambulances to each town may lead to higher casualties in large towns. Therefore, analyzing different equity policies is important in incorporating equity in decisions. As noted in Ref. 3, the implications of the options must be explored fully in the process.

Measurement

As discussed in Ref. 4, equity measurement involves comparing the effects of the decisions on the affected parties. Equity measurement is critical as it allows one to monitor and evaluate the degree of fairness achieved by the implemented policies and update policies if necessary.

An equity metric or a set of metrics can be used to evaluate the equity-based performance of a system. Each metric is formulated based on the specified equity elements: equity determinants, affected parties, and their attributes. Several equity metrics and objectives have been adopted in various problems and applications in the OR literature. For example, minmax type objectives that aim to improve the condition of the least advantaged have been widely used within the context of facility location and resource allocation problems. Twenty equity metrics relevant to facility location are reviewed in

Ref. 4. Other commonly used equity metrics include variance, range, mean deviation, and Gini coefficient. Given the number of alternatives in measuring equity, exploring the similarities and differences in solutions obtained from different metrics are important. Although there are several studies that compare different equity metrics, it is difficult to reach general conclusions regarding the use of a specific metric for different problems and settings.

Analyses that explore the trade-offs between equity and other objectives and evaluate the effects of various system aspects (e.g., regulations, budget) on equity can be insightful in understanding the use of different equity policies and metrics. Facility location and resource allocation literatures are relatively rich in this respect. For instance, in Ref. 6, the authors analyze the trade-offs between efficiency in terms of cost, and equity in terms of ambulance response time in providing equitable emergency medical service to people considering the inter- and intra-regional policies in Germany. Given the budget constraints in emergency care provision and the cost differences across regions, the policy makers face an important question: *whether to increase the total number of lives saved or provide equal access across regions*. Answering this question is difficult and open to debate. In Germany, policies for providing emergency medical services that emphasize efficiency over equity are followed across federal states; however, within each state equal access policies are mandated by law. Investigating the effects of various factors such as size of populations and regions, and regional income on the efficiency- and equity-based policies, the authors show that the actual implementation of the current equal access policy mandated by law values the lives saved in a rural area more than those in urban areas.

To summarize, there are many issues to be considered while incorporating equity in decisions. The literature indicates the importance of evaluating alternatives and analyzing implications while characterizing equity and selecting equity metrics. In the next section, we focus on equity as it pertains

to vehicle routing decisions in public service provision.

EQUITY IN ROUTING

In this section, we focus on equity issues within the context of vehicle routing. We review applications in which routing decisions affect equitable and fair allocation of resources, benefits, costs, or risks to the public. Table 1 summarizes the equity-related characteristics of the applications that integrate equity in routing decisions in the public/nonprofit sector. The table specifies the types of decisions addressed in different studies and provides examples of equity determinants and equity metrics/objectives for each application. In this section, we discuss several papers cited in Table 1 that highlight how equity is addressed in routing decisions.

The classical vehicle routing problem (VRP) determines a set of delivery routes for a fleet of vehicles dispatched from a depot to fulfill the demands of a set of customers, while minimizing total transportation costs. Since the introduction of the basic VRP over 50 years ago, the VRP and its extensions with different objectives and operational constraints have been widely studied. Extensions of the basic VRP include problems with multiple periods, customer and vehicle time windows, precedence constraints, heterogeneous vehicle fleets, and route length restrictions. Objectives such as minimizing the number of vehicles and routes or the length of the longest route have been used in various VRPs.

Many studies address vehicle routing for various commercial and public/nonprofit sector applications. Studies in commercial sector routing address delivery of a variety of goods and services. Several studies address problems of local city governments in providing public services such as street cleaning, electric meter reading, winter road maintenance, and waste collection. Other routing applications focusing on public services include public libraries, postal services, various health-care services such as blood collection, ambulance routing, home health care, disaster relief, material assistance, and mobility services.

Table 1. Routing Applications with Equity Considerations

Application (Example studies)	Decisions	Equity Determinants	Metrics/Objectives
Disaster relief distribution [11,12]	• Routing • Supply allocation	• Arrival time • Supplies	Equity metrics/objectives • [Minmax/Minsum] arrival time • Mean absolute upper semideviation of arrival times • [Minmax] unsatisfied demand percentage Other metrics/objectives • [Min] transportation cost (or time and distance)
Mobility services [10], [13–17]	• Routing • Location	• Travel time • Distance	Equity metrics/objectives • [Min] variation in route lengths • [Minmax/Limit] user travel time • [Limit] user walking time (or distance) to stops • [Limit] deviation from desired pickup/delivery time • Total absolute deviation from the mean travel time Other metrics/objectives • [Min] number of routes (or vehicles) • [Min] transportation cost • [Min] total route length (or time and distance) • [Min] total deviation from desired pickup/delivery times • Balance loads (number of users per route)
Food distribution [18–20]	• Routing • Supply allocation • Location	• Supplies • Distance	Equity metrics/objectives • [Max] expected minimum fill rate • [Min] total distance between unmet demands and facilities Other metrics/objectives • [Min] expected waste • [Min] transportation costs • [Min] facility costs
Hazardous material transportation [21–23]	• Routing • Location	• Risk • Distance	Equity metrics/objectives • [Minsum/Minmax/Limit] risk difference • [Min] average risk Other metrics/objectives • [Min] total risk • [Min] total cost (or time) • [Min] expected number of accidents

We observe that most of the routing studies in the literature address effectiveness and efficiency objectives; attention on equity-related issues has been recent and limited to few applications, mostly addressing public/nonprofit sector problems. In most commercial sector routing problems, equity is often not considered to be a factor affecting customer service. Equity in a commercial distribution system is studied in Ref. 7, which ensures equitable delivery times to customers in overnight delivery services by allowing a different set of routes on each day and limiting deviations from average delivery time through a set of constraints. Studies that explicitly consider equity as a major aspect in the public/nonprofit sector mainly address applications in the following areas: *disaster relief*, *food distribution*, *mobility services*, and *hazardous material transportation*, which are discussed in detail in the following sections.

We note that some studies that address routing decisions in commercial and public/nonprofit applications consider *route* and *load balancing* to ensure fairness for those who provide the service. More specifically, the problem seeks routes that yield balanced workloads and route distances/times to meet various regulations or for efficiency purposes [8–10]. Although balanced workloads for employees might have implications on the quality of service and fairness toward users, our focus is on applications that explicitly address equity and fairness for those served and/or affected by the operations, not the service providers.

Table 1 summarizes the equity-related characteristics of the applications that integrate equity in routing decisions in the public/nonprofit sector. The table specifies the types of decisions addressed in different studies and provides examples of equity determinants and equity metrics/objectives for each application. The following sections focus on each application area in detail. Specifically, section titled “Disaster Relief Distribution” discusses vehicle routing applications with equity considerations in disaster relief. The section titled “Mobility Services” presents several papers that consider equity in routing for mobility services such as school buses and

transportation services for the disabled and elderly. The section titled “Food Distribution” provides examples that consider equity in food distribution services. Finally, the section titled “Hazardous Material Transportation” discusses the equity issues in routing of hazardous materials.

Disaster Relief Distribution

Disaster relief services aim to save lives and reduce suffering after the onset of a disaster. The OR literature has widely addressed problems related to allocation and deployment of medical, police, and fire resources, in which equitable access is a major consideration. Most of the studies addressing these small-scale emergencies consider equity in terms of response time and coverage levels, and aim to position emergency resources to reduce the disparities in access to different regions. There has been an increasing attention in the literature for distribution problems in responding to emergencies caused by large-scale, high-impact disasters such as earthquakes, hurricanes, and floods. Large-scale disasters can be differentiated from smaller-scale emergencies by a number of aspects including their low frequencies and high-impacts. Once disasters occur, they are likely to create large demands for a variety of supplies at locations that may spread over a large area. The extent of demand created for relief supplies, staff, and services, combined with infrastructure difficulties, challenge the resource capacities of relief organizations in delivering aid. Owing to scarce logistic resources, it is typically very difficult, if not impossible, to immediately satisfy the entire relief demand. Therefore, allocating the available supplies fairly and equitably is a major concern in disaster relief. Moreover, response time equity is still critical in responding to large-scale disasters, especially during the initial days of response when search and rescue efforts continue, medical attention is vital, and time is the most valuable resource.

The majority of studies in the literature that address relief distribution problems use network flow type formulations [24–26]. Notably, in Ref. 26, the authors incorporate equity in their relief distribution model; a fill

rate-based equity objective that maximizes the minimum demand fraction is used in addition to efficiency objectives such as setup, operational, and transportation costs, and effectiveness objectives such as total travel time.

There are few studies that consider equity in classical vehicle routing type formulations for relief supply distribution. Equitable decisions are considered in local distribution of relief aid in Refs 11, 12. In both studies, the affected parties are defined as spatially distributed populations. Also, both papers incorporate equity in their models through defining equitable objectives. Specifically, in Ref. 12, the authors focus on evaluating two objective functions to ensure equity in routing decisions: minimizing the maximum arrival time of supplies and minimizing the average arrival time of supplies, which are analogous to minimizing makespan and sum of completion times in scheduling problems, respectively. They explore the potential impact of using these objective functions and compare solutions with those obtained with the traveling salesman problem (TSP) and VRP with the traditional objective of minimizing total travel time. Specifically, they analyze the relationship of the minmax and minsum objectives with the traditional minimizing total travel time objective and develop bounds on the performance of the new objectives for both TSP and VRP. It is shown that the new objective functions ensure better response times for the demand locations that are served later in a route. Also, average deviation of arrival times from the mean decreases, at the expense of reduced efficiency; that is, increased total route length.

In Ref. 11, routing and supply allocation decisions are considered jointly. The major problem is fair distribution of multiple types of supplies in a relief network. This study does not consider response time equity in terms of arrival times of supplies to the demand locations on each route; rather, delivery scheduling decisions are driven by supply allocation decisions and total transportation costs over a planning horizon. Given the supply, vehicle capacity, and delivery time restrictions, the authors address the problem of determining delivery

schedules, vehicle routes, and amounts of supplies to be delivered from a depot to demand locations during a relief planning horizon, whose length is unknown *a priori*. In characterizing equity in supply allocation, the authors capture criticality of supplies for different population groups by assigning penalty weights for unsatisfied demand at each location. Equitable allocation of relief supplies among demand locations is ensured by minimizing the maximum (weighted) unsatisfied demand percentage over all demand locations for each period. An efficiency objective based on total routing costs is also considered; however, decisions become mostly driven by supply allocation decisions as the importance of transportation cost is decreased through assigned weights. In their analysis, Balcik *et al.* [11] observe the effects of demand amounts, penalty weights, and remoteness of demand locations to the depot on supply allocation decisions.

Mobility Services

In this section, we focus on equity considerations in routing for mobility services. Examples of mobility services include school buses and transportation services for the disabled and elderly.

The school bus routing problem determines routes for public school buses to transport spatially distributed students from their residences to and from schools. The major considerations are efficiency and equity. Efficiency can be characterized by minimizing capital and transportation costs associated with operating buses, which alone might yield an inexpensive yet inequitable solution. Balanced bus route lengths and loads are the most frequently used equity indicators in school bus routing literature, which are incorporated in the models either in the objective function or the constraints; see Ref. 15 for a review of objectives and constraints used in school bus routing.

An urban school bus routing problem is considered in Ref. 13. The authors developed a multiobjective mathematical model that locates bus stops, assigns students to bus stops, and determines the vehicle routes

jointly. Equity is ensured via a set of objectives and constraints. In addition to balancing students travel times on buses, the walking distances of students to and from bus stops is also considered as an equity determinant. Each student is assigned to a bus stop such that each student walks less than the maximum walking distance, a constraint required by the school board. Variation in the route lengths (in terms of number of stops) is minimized. Finally, each bus route transports approximately equal number of students (i.e., balanced loads) to reduce the likelihood that some routes exceed capacity in the future. As such, load balancing is also an efficiency objective since it includes costs of reoptimization if new students are added to the system.

City characteristics can add further aspects to consider in modeling school bus routing problems. For example, a school bus routing problem in New York City is modeled in Ref. 10. The authors introduce mixed loads and multiple drop-off points in the model such that students from different schools may be allocated to the same bus. This flexibility can increase efficiency. The authors consider the routing problem in the mornings, which requires a higher number of buses due to more constraining time windows and traffic congestion. They note that a maximum distance constraint might be perceived as inequitable for students and parents if applied uniformly, since students whose bus stops very close to school might travel longer times than desired. Therefore, student-specific travel time constraints are used to ensure equity.

In Ref. 14, school bus routing in a sparse rural area is considered. Here students may experience longer travel times and greater variation in travel times, as compared to students in urban settings. Therefore, the maximum travel time is the major concern in rural school bus routing. As a result, in rural areas, buses reach an allowed route length in terms of time before they reach their maximal physical capacity. The model in Ref. 14 contains two objectives that are somewhat conflicting: (i) an equity objective of minimizing the maximum route length, and hence maximum time in the bus, and

(ii) an efficiency objective that minimizes the number of buses.

Similar equity objectives and constraints are relevant to other mobility services such as transportation for the disabled. These problems can be formulated as a dial-a-ride problem (DARP). In DARP, an origin and a destination is associated with each transportation request and each route starts and ends at a depot. DARP is a variation of pickup and delivery problem, in which people are transported door-to-door in groups or individually; see Ref. 27 for a review.

As discussed in Ref. 27, the efficiency objective of minimizing costs must be balanced against an objective of reducing user inconvenience in terms of long ride times and large deviations from desired departure and arrival times. Note that maximizing total effectiveness and quality of service does not necessarily lead to an equitable solution; either the worst-case service level over all users or service level differences among users or user groups must be explicitly considered for fairness. An example study that considers equity is Ref. 17, which considers the problem of meeting transportation requests of disabled people in an urban area. Transportation requests are known in advance and special types of vehicles may be needed to transport each user. The authors impose restrictions on maximum ride time for each user proportional to the direct travel time between the user's origin and destination.

Another study that focuses on free transportation services provided to disabled people by a nonprofit organization is Ref. 16. Vehicles transport people from their homes in the mornings to a training center, and return them home in the evenings. Working with the organization, Ref. 16 chooses the objective of minimizing total trip times by all vehicles as a proxy for cost subject to constraints on the minimum and maximum trip time for each vehicle and maximum and minimum number of seats occupied in each vehicle. An objective that aims to equalize trip times for each vehicle to prevent some trainees from excessive travel times is not found as a critical objective for the organization. As a result, while improvements are obtained in terms of travel times, distances and balanced loads, a

less equitable solution is obtained in terms of vehicle travel times.

Food Distribution

Similar to the studies discussed above in mobility services, OR methods can be used to improve food distribution services in communities. In Ref. 19, the authors consider collection and distribution of perishable food for a regional food bank. Each day, vehicles collect food from donor sites and deliver the food to recipient agencies on the scheduled routes. Donations and agency demands are observed upon the visit of the vehicles to the sites. This problem is formulated as a sequential resource allocation problem considering a single commodity. The authors develop allocation policies to provide equitable and sustainable service to agencies. Both throughput- and equity-based objectives are considered. It is shown that an objective that minimizes the expected waste and maximizes the total distribution results in inequitable solutions in terms of large discrepancies in fill rates for the agencies, whereas minimizing maximum expected fill rate tends to find an equitable solution with near-minimum waste. However, due to the mathematical structure of this equity-based objective, the existing methods from the commercial sequential allocation research are not directly applicable. Therefore, new solution methods are developed to solve the food distribution problem.

Another study that focuses on food assistance is Ref. 18, which considers distribution of hot meals to spatially dispersed homebound elderly people. This service is commonly known as “meals-on-wheels,” has also been studied in Ref. 20. In Ref. 18, the problem is formulated as an integrated location-routing problem, which involves determining kitchen locations and vehicle routes. Since the entire demand may not be satisfied using available kitchen capacity, an objective is to locate kitchens while unmet demand is fairly distributed over the region. This equity objective is modeled by minimizing total distance between unmet demand points and their closest kitchens. Other objectives are efficiency (minimization of fixed and variable facility

costs and transportation costs) and effectiveness (maximization of total throughput).

Hazardous Material Transportation

Hazardous materials such as radioactive materials, explosives, infectious substances pose a threat to the health or safety of people; therefore, minimizing population exposure when storing and transporting these materials is important. In hazardous material management, it is critical to obtain politically acceptable solutions that reduce safety risks and perceptions of injustice among local communities.

The problems related to locating sites for storing and disposing these materials and transporting the material from collection points to disposal sites have been addressed by a large body of literature; see review in Ref. 28. When optimizing the location of disposal sites, the general approach is to seek sites that are far from population centers to minimize risk. However, if facilities are located too far from urban areas, transportation costs tend to increase. Facility location decisions must incorporate these trade-offs, as well as fairness to all populations, recognizing that only equitable solutions would be accepted by communities.

In routing vehicles carrying hazardous materials, the critical issue is to limit and distribute equitably the risk over the geographical crossed regions [21]. While carriers focus on transportation costs, regulatory government agencies need to consider spatial risk equity to prevent perceptions of injustice that may result in public opposition to the use of nearby passageways and also excessive usage of some road segments, which may increase the chance of accidents [28]. Cost minimization approaches tend to ship large quantities over the inexpensive routes, whereas an equity objective may lead to transportation of smaller quantities over a large number of routes hence reducing the maximum exposure faced by each individual, which would increase transportation costs [22]. Although distributing risk over many routes reduces the risk to any one individual, the number of people exposed to risk may increase. Various multiobjective approaches are used in the literature to capture the trade-offs between

these objectives. Risk equity is modeled and assessed in a number of ways; for example, equity is ensured along the arcs, zones, or paths in a network. We provide a sample of equity objectives in Table 1.

Discussion

These applications summarize the main equity-related issues addressed in vehicle routing literature. Equity is defined, incorporated, and measured in models in different ways. As observed in Table 1, minmax and deviation type metrics and objectives are most frequently used. However, in general, types of equity metrics used in routing applications are relatively limited, for instance, compared to facility location applications.

We observe that equity is more frequently addressed in routing problems related to hazardous material transportation and various mobility services compared to other public services. Indeed, there are few examples that discuss equity in the distribution of supplies for disaster relief or other nonprofit operations, although we have seen a recent increase in these areas. Moreover, few studies discuss and compare the characteristics and implications of different equity policies and metrics or analyze the trade-offs between equity and other objectives such as effectiveness, efficiency, and flexibility.

Finally, most of the applications discussed in this article use mathematical modeling and heuristics. Since the VRP is NP-hard, incorporation of additional equity-related aspects usually brings additional challenges in solving problems. Moreover, resource allocation and facility location decisions are considered jointly with routing decisions in many applications further increasing the problem complexity.

CONCLUSION AND FUTURE RESEARCH

This article explores equity-related issues in the public and nonprofit sectors, focusing on vehicle routing applications. We discuss how equity is approached in OR in general and review studies from the literature that incorporate equity in vehicle routing applications.

Discussions and analyses regarding equity characterization and measurement are limited to few examples in vehicle routing applications. Therefore, future research can address various issues in studying equity in vehicle routing. For instance, implications of using different equity metrics can be explored for different problem settings in various application areas. Campbell *et al.* [12] show that modeling the delivery of relief supplies as a traditional TSP can double the latest arrival time to an aid recipient. Future work should continue to evaluate the trade-offs between efficiency and equity.

Additionally, methodological and practical implications of using different equity principles and policies can be explored. Solution approaches for nonprofit agencies often must focus on simplicity rather than on exploitation of technology. For example, the authors in Ref. 20 worked with meals-on-wheels to improve the distribution of lunches to the elderly. Meals-on-wheels needed a solution approach that could adapt to their changing client base without the use of computers. The project led to the development of a solution approach, based on the concept of space-filling curves, which could dynamically change routes, using only a map of Atlanta and two Rolodex files. The travel times of routes obtained with this method were generally within 25% of the shortest possible routes.

Studies addressing various facility location and resource allocation problems discuss the characteristics that are desirable when selecting equity metrics. For instance, criteria such as Pareto efficiency and principle of transfers are considered as minimum requirements for fair resource allocation. Future research may explore such criteria within the context of vehicle routing.

In providing public services, routing and resource allocation problems are often considered together. Future research can address integration of available resource allocation policies in the literature with routing decisions. For instance, in Ref. 29, the authors study a food allocation problem in a disaster relief setting and propose an equitable policy that considers two levels of food supply. Specifically, the proposed policy evaluates

the starvation level of each demand region before proportionally increasing the allocation amounts to reach a healthy existence level. The results and algorithms in such resource allocation studies can be used in developing solution methods for integrated routing and resource allocation problems.

In most routing applications, populations affected by decisions are assumed to be uniform while characterizing equity. This is often due to difficulties in capturing and quantifying differences among populations. For instance, identifying vulnerable groups and quantifying the criticality of emergency supplies at different locations are challenging in a disaster relief environment. Further research might explore how to incorporate the attributes of the affected parties in decisions.

Finally, future work may consider fairness in a multiple agency setting. Currently, most studies consider a single agency following a single equity principle. However, recent disasters such as Hurricane Katrina and the Asian tsunami highlighted the need for inter-agency coordination. It would be valuable to study the effects of multiple agencies implementing various policies in providing public service. Investigating the effects of coordination on equitable service provision might also have important implications in terms of efficiency and accountability of operations, particularly if agencies define their equity elements (equity determinants, affected parties, and relevant attributes) differently.

INTRODUCTION

From a business perspective, high economic growth cannot be achieved in the long run without protection of environmental and social needs but economic progress can also not be completely sacrificed for altruistic environmental or staff protection. The goal is rather to assure the long-term viability of a business model that can only be sustained if shareholders, suppliers, employees, and customers see a future in it [1]. Sustainability requirements can essentially be split into three interdependent dimensions encompassing environmental considerations, societal aspects, and economic development [2]. Sustainability as a concept provides a vision or roadmap for the future [3] but is difficult to grasp as related issues usually involve stakeholders with different interests and opinions regarding their responsibilities and sustainability requirements [4, 5]. Boundaries to an entity's impacts and associated responsibilities are difficult to assess and assign [6], often due to insufficient understanding of influences and interdependencies in a system environment [7, 8]. Many companies have started to implement sustainability into their internal operations, but it has frequently been emphasized that managers have to take their wider supply chains (SCs) into account as 50–70% of product value is actually derived through the SC [9, 10]. The

areas of sustainability and supply chain management (SCM) are characterized by inherent complexities, making it challenging to integrate sustainability considerations into SC decisions. However, examples have shown that making sustainability a strategic imperative helps overcome such challenges [11]. Many companies have recognized this pressing need and best-in-class companies take environmental initiatives and social responsibilities seriously [12].

Research Motivation and Objectives

Sustainable supply chain management (SSCM) has emerged as a relatively new field of research and practice in order to foster the integration of sustainability into SCs. While SSCM has become an enduring research area, there is a lack of conceptual theory development backed by rigorous research approaches [13–15]. SCs are complex structures that can span across multiple tiers of suppliers and customers [16, 17]. SC issues such as maintaining visibility, dependence on collaborative practices, or accurate performance measurement reach a new level of importance and difficulty when environmental and societal considerations are added to economic necessities. Theoretical understanding of sustainability requirements in SCs is limited and there is a lack of knowledge with regard to practices, methods, and prerequisites for SSCM. Accordingly, the currently available SC principles, frameworks, and models are not designed to meet these challenges and generally do not allow the transformation of existing SC processes toward a sustainable focus. Hence, theoretical and procedural support is required in the form of conceptual insights and practical approaches to address the challenges outlined.

On the basis of these motivational aspects, this article aims to identify practical tools and theoretical ideas that can help SC managers to implement sustainability into their operations and that furthermore hold the potential

to overcome the many systemic challenges. Furthermore, this article synthesizes these aspects within key elements of SCM. This not only provides context and tangibility to the review but also directly demonstrates the applicability of the aspects discussed.

DESCRIPTION OF THE REVIEW PROCESS

A literature review is “a systemic, explicit, and reproducible method for identifying, evaluating, and synthesizing the existing body of completed and recorded work produced by researchers, scholars, and practitioners” [18]. Previous reviews have focussed on providing a descriptive analysis of related literature [13–15, 19–22] in order to provide structure to the field but did not necessarily concentrate on content. This article addresses the need to discover and summarize the conceptual content of aspects relevant to SSCM and thereby contributes to theory development and practical application.

Identification of Relevant Material

The review process relied on the use of multiple databases and appropriate keywords. The following databases that focus on the fields of business and economics were utilized:

- ABI/INFORM
- ACM Digital Library
- Business Source Premier

- Emerald
- SCOPUS
- Science Direct

The keywords shown in Table 1 were searched for within each of the databases. Firstly, the primary keywords were used in order to identify influential articles within the broader area of SSCM. The search then turned to more specific topics in SCM, that is, the secondary keywords. These were used in conjunction with the primary keywords in order to synthesize methods and tools specific to these SCM areas.

The primary keywords are essentially a deconstruction of the term *SSCM* and thus reflect how different publications may have referred to it. Using them in conjunction and separately allowed to identify a range of applicable publications. These articles provided the background knowledge for this review and allowed to delineate the field of study. The rationale for concentrating on certain SC issues, and hence the selection of secondary keywords, was motivated by the goal to deliver an extensive but nevertheless concise review. An overview of what SCM essentially entails can be derived from definitions. While some authors focus mainly on material flows and coordination efforts [23], others emphasize managerial and network perspectives [24]. A more holistic view of SCM is generally accepted now which includes the integration of business processes, management decisions, and activities

Table 1. Keywords and Synthesis

Primary Keywords	Secondary Keywords	Synthesis
• Supply chain • Sustainability • Sustainable • Sustainable supply chain management	• Contracts • Customer value • Distribution • Information technology (IT) • Inventory • Measurement • Network • Outsourcing • Partnership • Procurement • Product design • Strategy	• Approaches • Ideas • Methods • Practices • Results • Tools

across the entire SC [25]. On the basis of this realization, it was deemed best to focus on recognized key issues in SCM to guide the selection of secondary keywords. The chosen SC issues are derived from seminal sources in the field [26, 27] and range across strategic, tactical, and operational levels. They were thus considered to be a useful guide toward functions and influential factors that are likely to have a direct impact on the sustainability of an SC as well. They are reflected by the secondary keywords displayed in Table 1 and investigated through a sustainability lens in this review. In line with the aims of this article, relevant tools, methods, and ideas were synthesized. Owing to the choice of primary and secondary keywords, these are directly associated with sustainability considerations and the key SCM issues.

Content Analysis

A content analysis facilitated the systematic analysis of the identified material, akin to previous reviews in the field [13, 22, 28]. As outlined, the material was identified based on keywords. These superimposed categories were then further utilized to guide the analysis of the material and furthermore to structure this article. As indicated under 'synthesis' in Table 1, the identified material was closely examined in order to discover relevant applications and ideas for SSCM. The relevance of content was judged qualitatively, that is, by drawing a direct connection to sustainability in SCs, but more quantitative aspects were also considered including the currency and impact of reviewed publications. As a review, this article relies on well-recognized material for guidance and structure while the synthesis draws mainly on fairly current publications. This is also influenced by the development of SSCM as a field of research that has predominantly taken place from the mid-2000s onward [21, 22, 28].

Readers should be aware that there is some overlap between the secondary keywords and thus between the sections of this article. Categorized data can be interpreted in different ways [29], and hence, some of the reviewed material could have been included in multiple sections or additional sources

could have been considered based on the rationale employed by the researcher. Furthermore, additional keywords could have been considered. The use of superimposed keywords can be justified by the careful selection process based on acknowledged key issues in SCM and the aims of this article, that is, to provide a concise and timely review. While these potential issues need to be acknowledged, it can nevertheless be assumed that this article presents a wide-ranging and insightful overview of up-to-date methods and practices conducive to SSCM.

SUSTAINABLE SUPPLY CHAIN MANAGEMENT

Most research on corporate sustainability has focussed on manufacturing and management processes in single companies [30], neglecting SC issues as well as systemic linkages and relationships. It is the aim of this article to investigate strategies, methods, and tools that have the potential to support SSCM. As a starting point, it is therefore necessary to reach an understanding of what SSCM entails and identify influential factors that determine the sustainability of an SC.

SC activities add an increasing proportion of value to products and services [31], can provide competitive advantages [19, 22, 32], and may also account for adverse side effects [13, 33]. Dealing with sustainability-related risks and creating market opportunities [34] requires that sustainability considerations are embedded in SC operations and decisions [19, 22, 32]. A three-dimensional focus on economic, environmental, and social considerations is evident in most recent publications. Saying that, research on social SC aspects is lagging behind [21, 35, 36] while environmental considerations are predominant. Thus, there is a bias in SSCM research toward exploring environmental applications, which is consequently also reflected in this review article.

SCM as a research discipline has been approached from different directions, which resulted in a plethora of definitions [37, 38]. Similarly, various definitions of SSCM have been proposed over the years. Ahi and Searcy

[28] contrast these existing definitions, synthesize key elements, and define SSCM as:

the creation of coordinated SCs through the voluntary integration of economic, environmental, and social considerations with key inter-organizational business systems designed to efficiently and effectively manage the material, information, and capital flows associated with the procurement, production, and distribution of products or services in order to meet stakeholder requirements and improve the profitability, competitiveness, and resilience of the organization over the short- and long-term.

The definition shows that SSCM goes beyond traditional objectives of SCM as it involves the systemic coordination of SC resources and flows in accordance with sustainability considerations. Furthermore, the requirements of SC stakeholders have to be continuously assessed from short- and long-term perspectives. SC practice has to be informed by theoretical building blocks in order to deal with these complexities. Some useful higher level frameworks exist that outline supporting facets of sustainability in combination with SC considerations (Figure 1). As can be seen, application of SSCM demands that two or ideally all three sustainability dimensions are explicitly considered. This focus is also maintained

in this review article. In addition, more elaborate discussions of the theoretical underpinnings of SSCM or the development of this particular field of SC research can be found in the literature [13–15, 19–22, 28].

Network Structure

The network structure is a key element of SCM [16]. It is crucial to any SC and requires detailed information in order to make appropriate decisions including, for example, distribution strategies, the selection of warehouse locations and capacities, and production levels of products and plants. Furthermore, the transportation flows between different warehouses, production facilities, or SC members have to be determined. The general goal is to minimize the total costs related to production, inventory, and transportation while satisfying service-level requirements [26].

Winter and Knemeyer [14] elaborate on the importance of the network structure and interfirm relationships with regard to implementing sustainability. They summarize that a network needs to be flexible and adaptable based on partnerships in order to derive benefits for the SC. There is an emphasis on the need for coordinated and collaborative relationships between SC members. The relationships differ in that there may be ‘hard’

Figure 1. Facets of Sustainable Supply Chain Management [Source: Adapted from [19]].

relational ties such as material and monetary flows and ‘soft’ ties of friendship and information sharing. The traditional focus in SCM is on market and manufacturing issues and SC strategies are usually based on cheap transportation [39]. Poor design of transportation channels can lead to SC disruptions and higher environmental impacts. Requirements around reverse logistics, for example, returns and recycling, add further complexity [40]. Changes in market conditions, for example, rising fuel prices, can furthermore result in performance problems and risk of disruption demanding a sustainable orientation of the SC configuration [39]. Stringent controls of customer demand, manufacturing processes, and supplier performance have been associated with less uncertainty in the chain [31].

Schiller *et al.* [41] suggest to increase transport efficiencies through advanced transportation technologies, fleet differentiation, collaborative fleet management, load matching, and optimized scheduling. Potential outcomes are more appropriate vehicle selections depending on the transportation job while avoiding partial loadings and waiting times. Improved intermodal transitions can further minimize costs, congestion, noise, and pollution. More feasible supply sources and shortening of SCs present opportunities to mitigate the negative effects of distribution but may have to be promoted by policy efforts and weighed against purchasing costs, volatility risks, and infrastructural requirements [41, 42].

Reverse logistics is increasingly seen as an avenue to reduce SC waste and utilize resources from products at the end of their useful life [43]. Apart from utilizing obsolete products, reverse logistics can improve product designs as activities such as reuse, recycling, and remanufacturing come to the forefront [44]. Reverse logistics, however, also add to the complexities involved in network-related decisions [40]. Successful implementation of reverse logistics depends on whether monetary investments are warranted through economic benefits [30, 45]. Related research has revealed sustainability potential by reducing fluctuations of material costs, demand patterns, and repetitive

purchases [46]. The effectiveness of the idea has also been investigated by modeling the effectiveness of incentives such as rewards and advertising [47].

Another idea that influences network structures is industrial symbiosis or closed-loop SCs, which emphasizes reduction opportunities regarding system-level waste. It is based on utilizing the residual value of waste products from one operation as input material for other processes [30, 48]. Analyzing waste streams from an SC perspective can transform waste output from one company into value for the chain [48]. A high degree of cooperation and coordination, and hence exceptional relationship management, are required to facilitate such an improved flow of production by-products. In addition, any waste output has to be compatible with the input requirement in terms of quality, quantity, and logistics requirements. The high degree of interdependence also makes the system vulnerable to changing market requirements, for example, demand swings or price changes. Hence, industrial symbiosis holds potential in certain SC constellations but has limitations in terms of potential market risk and implementation difficulties [30].

Inventory Control

Inventories uncouple “the various phases of the process or service delivery system and thereby allow each to work independently of the other parts” [27]. Inventory control is vital for an SC as chain members have different requirements in regard to inventory size, reorder times, and demand of their process-related inventory and support inventory.

Inventory control is tightly linked with information technology (IT) and the availability of demand and supply information. These are crucial for reducing excessive inventory levels and associated costs caused by spoilage, insurance, theft, and obsolescence [49, 50]. Inventory control is therefore a priority for best-in-class companies and emphasis should be placed on accurate demand planning and forecasting to ensure optimized inventory levels [51, 52]. Demand amplification and the associated swings in inventories are also detrimental to sustainability goals and associated risks should

be decreased by better communication, inventory-related information exchange, and accepted mitigation strategies [53, 54].

The reduction of travel distances can support sustainability goals [41], suggesting a move from centralized inventories to several decentralized facilities, that is, increase proximity and accessibility to reduce transportation needs. Third-party logistics providers can help consolidate consignments, thus reducing costs, when dealing with resulting smaller shipping quantities. In addition, in case of supply disruptions, having larger amounts of inventory stored in various locations can reduce lead times for sourcing replacements and ensure general availability. Downsides are potentially higher fixed costs as more capital is locked in inventory while running additional storage facilities is likely to increase operational costs. Inventory holding costs are often higher than the generally assumed 20–25% but can add up to 60% of the cost of an item that stays in inventory for 12 months [51].

SC disruptions have negative economic impacts on the affected organisations [55] and are often due to shortages in supply and insufficient inventory levels. Single sourcing and lean supply strategies have resulted in increased dependence on suppliers. While such strategies often facilitate better cost control and help eliminate non-value-adding activities [17, 56], they can also make an SC more vulnerable to disruptions caused by, for example, natural disasters or political upheaval [57]. Risk management has become a major challenge in SCM [58] and possible risk mitigation options include a diversification of suppliers to provide backup sources for products and materials. Encouraging suppliers to establish additional supply locations and adding buffer stock for pivotal materials can provide further support to counteract SC disruptions [57].

Supply Contracts

Supply contracts generally specify the conditions of the relationship between suppliers and customers including pricing and volume discounts, lead times, or quality standards. Individual companies are traditionally mainly concerned with their own profitability

resulting in little attention paid to the effect of one's strategy and decisions on other SC members.

Building strong relationships between SC partners is crucial for SSCM as each SC member must meet sustainability criteria [59]. One way to ensure appropriate codes of conduct and supplier sustainability performance are audits that can include accreditation requirements, inspection of facilities, or reviewing documentations [60]. On the basis of such performance evaluations, supply contracts may be awarded, additional assessments may be scheduled, or certain conditions may be imposed on the supplier. Larger companies often require all their suppliers to obtain accreditation standards that force them to change their practices accordingly [61]. Management standards can contribute to sustainability performance [62, 63] and Pagell and Wu [64] emphasize that supplier certifications can specifically address social sustainability requirements, for example, child labor, worker safety, or working conditions.

Many companies tend to engage in collaboration only in order to facilitate assessments, whereas engagement in collaborative SC practices holds the potential to foster sustainability directly [65]. Instead of imposing sanctions, failure to meet supplier compliance standards can be addressed by joint efforts to develop necessary skills and procedures. Collaboration in supply relationships can be fostered through appropriate SC incentives and education across the tiers of an SC [66]. This can prevent issues such as concealing noncompliance or damaging a supplier's reputation and competitiveness, which in turn might lead to deterioration in sustainability performance. Dedication to partnerships can result in more supply options, higher transparency, more accurate performance assessment, and overall closer buyer–supplier relationships [67, 68]. An SC segmentation approach can help manage the complexities of collaborative arrangements by concentrating on critical SC partners [69].

Distribution Strategies

Distribution and transportation account for a high percentage of SC-related costs, making the distribution strategy a key issue in SCM. Logistics operations have also been identified as an area where most organizations can make sustainability improvements [70]. Distribution costs largely depend on the location of trading partners and the selected modes of transportation. The five commercially used transportation modes, that is, rail, road, water, air, and pipeline, differ significantly in terms of price, speed, and their share of goods moved [27]. Figure 2 does not include considerations regarding travel distances and only displays an approximated mix for developed economies. However, it becomes evident that selection of a ‘less appropriate’ mode can be costly in terms of money, time, and resources.

Low cost solutions that ensure the availability of goods and services are paramount for any SC. However, distribution strategies purely targeted at economic goals have begun to become obsolete as the environmental/social impacts and regulations are not considered [70]. Different distribution options and mode selections may be synergistic but can also create trade-offs due to incompatibilities. For example, lean and green strategies are often seen as compatible due to their focus on waste reductions, for example, the reduction of inventory and associated sourcing, producing, transporting, packaging, and handling activities. However, certain lean strategies, such as Just-in-time, are focussed on small lot sizes that require in fact more transportation, packaging, and handling [56]. Distribution strategies are often aimed at high product mobility to compensate for the prevalence of global, long-distance SCs. From a sustainability point of view, there are arguments against long SCs,

for example, vulnerability against world events, higher emissions, and difficulties to measure and assign externalities [41].

The optimization of distribution systems has long been a key goal for researchers and various techniques and solutions have been proposed. While not necessarily targeted at SSCM, the findings may also be beneficial from a holistic sustainability perspective. Overviews of such mainly quantitative optimization techniques are provided in more targeted articles [70]. Additionally, a variety of measures that can foster more sustainable distribution strategies can be identified [41, 56, 71, 72]:

- Increasing the efficiency of freight vehicles and use of alternative fuels
- Improved strategies for maintenance, disposal, and operator skill improvement
- Differentiation of the fleet, for example, smaller and nonmotorized vehicles
- More efficient scheduling and vehicle use, that is, increase in utilization
- Improved intermodal services and facilities through network redesign
- Policy efforts to promote shifting the truck-train breakeven point toward rail
- Ocean shipping reforms
- Slow steaming
- Shifting airfreight to high speed rail services
- Shipment consolidation
- Reverse logistics
- Redistribution of sourcing
- Carrier selection based on sustainability considerations
- Shortening of SCs
- Policies to promote shortening distances and reducing volumes of freight

Price per tonne/mile	Low	Pipeline/water	Rail	Road	Air	High
Speed, door to door	Slow	Water	Rail	Road	Air	Fast
% of goods moved	High	Rail	Road	Pipeline	Water	Low

Figure 2. Comparison of Modes of Transportation [Source: Adapted from [27]].

- Optimization of lot sizes
- Reusable packaging and containers

This list provides a series of distribution alternatives for SCs to explore and it has been shown that several of these options are already considered and applied in practice [73]. Maintaining decentralized local capacity and allowing for some slack resources also allow SCs to cope with uncertainties and risks of disruption [74]. Intermodal transport along with more appropriate, efficient, and cleaner forms of transportation can mitigate sustainability issues in distribution. As an example, slow steaming strategies are now widely employed in international shipping in order to cut emissions [72]. While high utilization remains important when selecting transportation modes, emission efficiencies have to be considered. For example, ocean shipping and rail have carbon emissions that are only a fraction of that caused by road haulage and airfreight [75, 76]. This is obviously of economic and environmental benefit and can furthermore foster logistics integration in SCs [77, 78]. A study among practitioners found that aspects of transportation, warehousing, and distribution have been neglected so far and emissions or energy consumption are not generally considered for supplier selection. Initiatives and sustainability objectives are also often not extended to second- or third-tier SC members [58].

Strategic Partnerships

Strategic partnerships and SC integration are necessary in order to stay competitive as companies increasingly compete on a SC level [79, 80]. Feasible SC partnerships are crucial considering the ongoing trends toward outsourcing, shifts to countries with low labor costs, reduction of physical infrastructure and inventories, and the vital role of SCs in providing delivery advantage [26, 27]. In such cases, consideration needs to be placed on indirect costs affiliated with intercontinental or long-haul SCs, including, loading, unloading, customs clearance, or transferring goods to warehouses [81]. Determining factors for choosing overseas suppliers

include, for example, supply structures, real-estate-related factors, and the characteristics of the actual industry [82]. An SC can be considered integrated when all product or service transfers are coordinated to manage costs and inventory levels while maintaining customers' delivery requirements. Planning activities and execution processes can be integrated through collaborative planning and vendor managed inventory [27].

One avenue toward sustainable competitive advantage is to create collaborative long-term relationships between SC partners [67]. SC collaboration was also found to foster internal company collaboration and improve service performance [83]. Harris *et al.* [40] suggest more horizontal and vertical collaboration between logistics operators in order to tackle sustainability challenges. Lee [84] points out the importance of long-term strategic relationships in order to support sustainability initiatives. A complete rethink of an SC structure may be necessary "including cutting out middlemen, changing suppliers and supply locations, taking a more holistic view of costs and benefits, and taking a longer term view of supplier relationships" [84]. It is emphasized that initiatives need to reinforce each another and that SC problems cannot be solved in isolation. More social and environmental SC control has been associated with financial benefits and long-term relationships that in turn support economic sustainability [1, 85].

Active management of strategic partnerships is crucial for sustained value and continuous improvement. Especially SC leaders or companies that are associated with the final product have to select their business partners with particular care to protect their reputation as they will be held responsible for unsustainable behavior within their SCs [86]. Relationship management programs have to ensure that relationships stay healthy by providing a platform for problem resolution, mutually beneficial continuous improvement goals, and control over performance objectives [51]. Two-way communication and mutual active engagement are pointed out as key to success. In order to manage related risks, implementation guidelines to implement

SSC practices can provide useful assistance, for example, Zhu, Sarkis, and Lai [87] develop and validate several measurements and underlying factors for the implementation of green SCM practices. Robinson [88] points out that sustainability requires the ongoing dynamic capacity to respond adaptively to changes. Hence, SC agility needs to be considered, that is, customer sensitivity, virtual integration, process integration, and network integration [89,90]. Customer sensitivity corresponds to the requirement to understand and quickly respond to market requirements through collaborative initiatives. Virtual integration is about accessing and visualizing information, knowledge, and competencies on an SC-level facilitated by information systems. Process integration highlights the interdependence of SC members, which is required to integrate key processes with their SC partners in order to manage change within their own organization and across the SC. Lastly, network integration demands a common identity, compatible information architectures and structures, and commitment to cooperation as well as performance measurement [89,90].

Outsourcing and Procurement

Outsourcing and procurement strategies determine whether a company decides to manufacture in-house or to buy from outside sources. Lakenan *et al.* [91] point out that outsourcing manufacturing functions allows companies to concentrate on their core capabilities while leaving production to suppliers with specialized knowledge. Other motivational factors include economies of scale at the suppliers' end as production volumes can be aggregated from multiple customers allowing to buy input material in bulk and at lower costs.

Similar to earlier business developments, sustainability may eventually become the norm, that is, an order qualifier [13]. Thus, sustainability needs to be actively encouraged by buyers so that sustainability performance can be marketed as an order winner [92]. Hence, outsourcing and procurement are crucial aspects in SSCM as "a company is no more sustainable than its SC—that is, a

company is no more sustainable than the suppliers that are selected and retained by the company" [92]. To support sustainable purchasing decisions, Pagell *et al.* [93] therefore propose a purchasing portfolio matrix taking into account transaction cost economics, the resource-based view, and stakeholder theory. The inclusion of other internal business functions in sourcing decisions can support the purchasing department by soliciting feedback and information on business objectives and strategies [51]. Krause *et al.* [92] suggest including sustainability as a competitive priority in purchasing and construct a purchasing model for SSCs based on the categorization of purchases into strategic, bottleneck, leverage, and noncritical as outlined by Kraljic [94]. Traditional competitive priorities in purchasing include quality, cost, delivery, and flexibility, which should be extended to include innovation. As a result, requirements for sustainable purchasing are derived for different product categories [95]:

- For strategic items, a focus on innovation is necessary to emphasize sustainability requirements for new product developments. Closer collaboration and transfer of know-how are decisive factors along with commitment to sustainability from suppliers.
- Bottleneck items put buyers in a dependent position making it difficult to assert pressure on suppliers. Industry standards for sustainable operations can be encouraged instead.
- For leverage items, emphasis should be put on recycling and waste prevention. Know-how transfer of improved practices across the SC is therefore important.
- For noncritical items, it may be easier to establish sustainability requirements due to a large supply base. Procedures regarding supplier selection and retention need to be adjusted accordingly, for example, certifications as selection criterion.

These purchasing requirements emphasize the need for SC collaboration and

long-term commitments between buyers and suppliers. Pursuing a sustainable sourcing strategy can be complicated by dynamic market requirements and globalization trends. Main driving factors for outsourcing are cost, flexibility, and concentration on core capabilities [91]. Global sourcing is often seen as the only option to gain a competitive advantage and is pursued especially by larger companies. However, it is often not supported by integrated global sourcing strategies [96]. Trade-offs between sustainability goals are often necessary, for example, maintaining control on working conditions or dealing with an increase in shipments along with potentially longer distances [67]. Cultural differences can present obstacles while effective supplier–buyer relationships are needed, which can be fostered through trust, commitment, and long-term orientation [96,97]. Thus, to support sustainable purchasing in increasingly global SCs, one needs to investigate the role of culture in creating and maintaining long-term relationships. Cannon *et al.* [97] point out that many uncertainties exist in this regard and suggest that an understanding of cultural values may help develop and improve relationships and increase the likelihood of long-term success.

Risk mitigation, for example, preventing SC disruptions is tightly coupled with sourcing decisions [51,57]. Sourcing decisions can be supported by risk mitigation methodologies including the identification of risk elements, determination of associated risk probabilities, assessment of potential financial impacts, and the prioritization of risks for monitoring and prevention [51]. Local production has been suggested in order to increase self-reliance and security of supply [41]. Diversification of the supply base and higher safety stock for critical items [57] along with compliance management, production standards, and real-time communication [98] can also help absorb the risks associated with sourcing. An associated approach is the ‘supply chain risk management process’ that classifies risk into nine separate categories along with feasible mitigation strategies [99]. These include phases such as risk identification,

monitoring, and controlling through risk analysis. Risk factors in SC sourcing cannot be viewed as disconnected and managers should, hence, pay attention to supplier relationships, information sharing, trust building, and collaboration [100].

Product Design

Decisions associated with product design can directly influence, for example, inventory holding or transportation costs by giving consideration to economic packaging and transportation, concurrent and parallel processing, and standardization [26]. Through SC design efforts, SC members can benefit from each other’s expertise while being able to concentrate on their own competencies. Suppliers can align their processes to new product requirements before the design is finalized and point out potential problems early on. Customers, on the other hand, can influence the product development so that the final design will specifically meet their requirements [101].

Developments in SC practice show that sustainability concerns are being addressed by modifying product design and packaging, incorporating sustainability initiatives into SC strategies, and establishing carbon management goals [58]. Product designs often reflect the prevalent market conditions during their creation, for example, products tend to be geared toward full replacement instead of repair when wages outweigh material costs. Extending product life helps reduce product obsolescence [102]. Modular product designs can be beneficial as they allow for easier repair, remanufacturing, and automated problem diagnosis. Furthermore, modular designs facilitate reuse, recycling, and disposal because of easy disassembly [103]. Reduction and reuse of product packaging also present opportunities to reduce SC impacts [76]. Factors that are often neglected in product design are by-products created during production, distribution, product use as well as disposal. SC integration can help mitigate associated negative impacts [67].

To support the aims of SSCM, product design along with product life cycle considerations can be of special importance [104]. Product life cycle management can help mitigate

sustainability risks by maintaining visibility, interoperability, and information exchange between SC partners and focussing on the impacts of a product throughout its entire life [42]. Life cycle assessment (LCA) can be useful to decrease adverse product impacts during preproduction, production, usage, and after disposal. It has been pointed out as one of the main methods to integrate environmental thinking into SCs since it emphasizes proactive behavior and demands careful supplier selection [42]. LCA thinking has also been associated with the creation of new business opportunities as previously unidentified problems may be recognized by SC partners [105]. However, there appears to be a lack of guidelines with regard to such integrations. SCs may require significant restructuring to integrate LCA and different types of SC structures demand different kinds of LCAs [106]. SC practices have impacts during each of the product life cycle stages and product design should reflect this accordingly, for example, ascertain that products can be manufactured, transported, used, and disposed of through sustainable practices [42]. It has, however, also been pointed out that LCA does not consider the entire SC and that a shift toward a holistic SC focus is required [71].

Design strategies targeting sustainability challenges include “Design for Environment” (DfE). DfE aims to reduce the amount of energy and material needed for the provision of goods and services by including environmental considerations in all design stages, for example, from project definition to concept and prototype development, field testing, and commercial launch [104]. Regulations already force companies to recycle or to be responsible for disposal of their products; for example, legislations in the European Union require manufacturers to design their cars so that 95% can be recycled [107, 108]. Thus, DfE and LCA are tightly connected and are useful concepts for developing and maintaining SSCs [104]. Borchardt *et al.* [109] point out that DfE is rarely considered by small and midsized companies due to, for example, lack of expertise, appropriate design tools, or missing know-how about how to change existing processes. Such difficulties have to be overcome in SCs as products are often

designed and built through an SC effort. Larger SC members with more resources and expertise may need to support their smaller SC partners in order to fully utilize the advantages of DfE and LCA.

Information Technology

Company success increasingly depends on SC coordination as much of the revenue is usually generated through the SC [31]. IT is one of the key aspects that drive SC efficiency nowadays. Information sharing within firms and across SCs is needed in order to enable and to fully exploit the power of SC integration [110]. To truly support the aims of the SC, it becomes increasingly important to store and communicate the “right kind” of information. Organizations and supply networks need to share information so that they are able to adapt quickly to changing requirements but are not overwhelmed by unnecessary data [26, 111]. IT systems should support easy retrieval and viewing of required data in order to make sound business decisions and avoid complicated workarounds [51]. Appropriate IT is of importance for exchanging inventory data and sales information. It can thereby support the reduction of cycle times and inventory costs while improving order fulfilment and customer service [50, 112]. Thus, information sharing impacts economic performance, for example, inventory levels and respective costs can decrease with an increase in the level of information sharing [49]. With smaller organizations also being able to afford and adopt IT, efficient information sharing and communication within the SC has been increasing [113, 114].

The control of sustainable practices is complicated in SCs [67] demanding compatible and user-friendly IT to support performance measurement. Considering the linkages and dynamics in a system like an SC is of special importance for accurate performance assessments [115]. Performance measurements in SCs have, however, been described as being beset by a lack of connection with strategy, focus on cost to the detriment of noncost indicators, lack of a balanced approach, insufficient focus on customers and competitors, focus

on local optimization, and a lack of system thinking [116]. In spite of such challenges, accurate performance measurements are essential for any improvement activity [117]. Indicators are commonly used in the context of sustainability in order to analyze progress and to communicate developments [118]. Thus, the effective communication and evaluation of an SSCM strategy requires a common language, facilitated through the use of KPIs to support informing, steering, and controlling [119]. Appropriate selection of performance measures as part of an SSCM strategy is essential to prevent functional silos and one-sided assessments. Standard measures to assess supplier performance include, for example, profitability, growth, service levels, technology use, or trade volumes [113]. However, SC performance cannot be holistically measured by financial ratios and logistics indicators alone but is affected by intraorganizational issues, the quality of relationships between SC members, as well as demands from customers and stakeholders [77]. Qualitative indicators are often neglected as it is sometimes neither financially viable nor practical to record qualitative data [119] but demand attention as some sustainability aspects may only be captured qualitatively. In support of SSCM, IT must capture the total cost of SC activities from the extended SC including usage of resources and creation of by-products [102]. A balanced approach has been prescribed to accurately evaluate SC performance including financial and nonfinancial measures classified according to strategic, tactical, and operational levels [120–122]. Researchers have made some advances in this area and have described approaches to develop and implement balanced scorecards specifically targeted at supporting SSCM [123, 124].

Customer Value

It is important for any company to assess the value offered by their services and products as perceived by the customer. This perception can be categorized into conformance to requirements, product selection, price and brand, value-added services, and relationships and experiences. SC success as a whole is also dependent on the value

provided to the end-customer, value being “the measure of desire for a product and its related services” [110]. Bowersox *et al.* [110] therefore emphasize that firms have to extend their management practices beyond suppliers and include suppliers’ suppliers so that their views on resource needs and constraints, threats, opportunities, and weaknesses can be considered.

Integrating sustainability considerations as a strategic priority can lead to improvements with regard to image and reputation [125]. Customer interest in SC sustainability is increasing, for example, the majority of customers who engage with third-party logistic providers are sensitive to sustainability issues [73]. Potential advantages of an SSC can go beyond reputation benefits including reliable long-term supply sources, increased visibility and control throughout the SC, reduction of price and volume volatility, improved quality, and increased efficiency [84]. The customer base may furthermore be extended toward environmental and socially conscious customers [67]. These aspects may help ensure the profitability of each company in the SC.

On the flip side, the current focus on sustainability and associated consumer preferences has also led to green-washing practices that in turn resulted in growing scepticism among consumers [126]. In order to reap the benefits of sustainable practices, SSCs have to distinguish themselves from SCs employing green-washing practices. Sustainability communication can provide customers with information about a SC’s practices and values. Suitable instruments include sustainability reports akin to financial reports, certifications through independent organizations, or the use of eco-labels for ones offerings [126, 127]. Success depends on such instruments to influence the acceptance level of customers, that is, customers have to see value in a SC’s sustainability efforts [126]. Especially in larger companies it has become common to report on SC sustainability as part of their corporate sustainability reports [12]. Such voluntary efforts have been described as crucial in order to effectively address industrially induced problems [128].

Table 2. Overview of SSC Characteristics

SCM Elements	Summary of SSC Characteristics	Tools and References
Network configuration	Elimination of distribution-related wastes and incorporation of sustainability costs. Developing partnerships and collaborating toward SC flexibility and a true SC perspective reaping the benefits of an advanced SC configuration	Marketing and manufacturing issues [31] Developing partnerships [14] Increasing transportation efficiencies [41] Reverse logistics [43] Industrial symbiosis [30] Closed-loop SCs and green SC innovation [48] Reduction of transportation distances [41] Control and capacity considerations [49] SC disruptions [55] Demand amplification [54]
Inventory control	Strategic placement of inventory to ensure accessibility. This may include the reduction of distances, altering distribution paths, and mitigating SC disruptions	Relationship building [59] Standards and certifications [62–64] Collaboration, incentives, and supplier education [65, 66] Intermodal transportation [75]
Supply contracts	Outlining multidimensional sustainability requirements and emphasizing collaborative relationships. Introduction of common standards and performance assessments	Sustainable distribution strategies [41, 56, 71, 72] Sustainability and other SC approaches [56, 70] Collaborative relationships [83, 84] Active management and continuous improvement [51] Agility and ability for change [89, 90]
Distribution strategies	Emphasis on intermodal connections and a high degree of accessibility. Use of suitable transportation modes, reduced freight distances, and efficient freight vehicles	
Strategic partnerships	Integrated planning and collaborative environment among strategic SC partners. Active SC management in order to develop mutual benefits with suppliers and engage in continuous improvement	
Outsourcing and procurement	Sourcing and procuring to support long-term SC goals with sustainability as a core competency. Availability of mitigation plans to deal with changing market conditions and supply disruptions	Purchasing priorities [92, 93] Supply risks [98–100] Buyer–supplier relationships [97]
Product design	Considers full life cycle of products along with reverse logistics to eliminate occurring waste and ensure nonharmful design. Utilize product design to improve sustainability of the SC	Product design and life stages [102, 103] Life cycle assessment [42, 106] Design for environment [104, 109]
Information technology	Integrated sustainability-oriented systems that allow for access to all relevant SC data. IT that supports balanced performance assessments, effective communication, and information sharing	Measurement in SCs [113, 115, 116] Key performance indicators [118, 119] Balanced performance measurement [120, 121] Balanced scorecard for SSCM [123, 124]
Customer value	The customer perception of value drives SC processes. Customer value is supported by improved SC performance, collaboration, long-term relationships, sustainability measure, and their communication	Sustainability and the customer [67, 73, 84, 125] Green washing practices [126] Sustainability reporting and compliance management [12, 128]

OVERVIEW OF KEY FINDINGS

The previous section provided an overview of important SC issues and sustainability concerns, outlining potential avenues for practitioners on how to move their SCs into a more sustainable direction. The interconnected nature of SC elements, sustainability concerns, associated requirements, and potential actions to take is also emphasized. It presents a starting point for decision makers in SCs that can guide a long-term SC strategy as well as operational decisions. As a key insight, this review has shown that companies should avoid disconnected ad hoc sustainability initiatives in their SCs. They should instead focus on a holistic SSC strategy with a long-term focus and align their practical choices accordingly.

On the basis of the review of key SCM elements through a sustainability lens, a summary (Table 2) was constructed that summarizes SSCM practices and identifies related reference material.

CONCLUDING COMMENTS

It can be expected that sustainability in general, and in extension the topic of SSCM, will continue to be of interest for researchers and practitioners alike due to the persisting nature of the underlying causal linkages [129]. The requirement to consider sustainability has been widely recognized by regulatory bodies and companies and is also increasingly demanded by consumers. As this review has shown, SCs have a crucial role in this endeavor and are well positioned to support sustainable development due to their wide-ranging impacts and influences. Decision makers in SCs are therefore tasked with strategic sustainability orientations and operational shifts. The thematic review of the literature has shown that traditional SC structures and operations may have to be redesigned in order to face current and future sustainability challenges. It became evident that the focus of many approaches is on isolated SC issues and it is usually not clear how these could be tailored and integrated as part of a more complete SSCM strategy. SCs and

sustainability requirements are both characterized by complex interactions that have to be understood in order to shape such a strategy. Customizable, prescriptive frameworks and models are required that can guide and facilitate strategic SSCM transformation and development while embedding more specific tools and methods at operational levels.

While this article can only provide a brief overview, many applicable methods, tools, and sustainable practices could be identified. The findings of this review can be of use for academic researchers and SC practitioners alike. Researchers are presented with a summary of methods and tools that hold the potential to support SSCM. It thereby informs academics of the current state of the field and points them toward new research directions. Practitioners can capitalize on this study by reviewing approaches that have been found feasible to support SSCM. While actual implementations in SCs depend on particular contexts, practitioners can use this review to identify potential avenues for sustainability development and understand the situations in which tools or ideas have been successfully applied in practice. Readers should be aware that the field of SSCM is characterized by rapid expansion. Research insights and SC practices continuously develop, making a truly comprehensive overview impossible. Hence, it needs to be acknowledged that ideas may have been overlooked in this review due to the dynamic nature of the field and the reliance on primarily academic sources. SSCM scholars are therefore advised to actively update their understanding as required based on new additions to the literature.

The high levels of oil consumption and obesity in the United States have become important socioeconomic concerns. In June 2008, the national average price of regular unleaded gasoline exceeded US\$4 for the first time in the United States, more than tripling its price since June 2003 [1]. These record fuel prices, coupled with growing concerns over carbon emissions and their role in global warming, have piqued the national interest in reducing fuel consumption. At present, the United States is responsible for approximately 25% of the world's daily oil consumption, with two-thirds of this amount devoted to the transportation sector [2]; these facts suggest that changes in the transportation sector can lead to substantial reductions in oil consumption.

As oil consumption has become a national concern, so have the growing rates of obesity in the population, which have been rising for several decades. In 2004, more than 32% of US adults were estimated to be obese, up from 12% in 1991 [3,4]. This increase has occurred despite increasing evidence that individuals who are obese are more likely to suffer from health conditions such as coronary heart disease, type 2 diabetes, and high blood pressure [5], as well as the proliferation of government programs designed to promote healthier lifestyles.

These two issues may seem unrelated. However, several studies have demonstrated

that there is a link between the incidence of obesity and automobile use. A study of transportation and health trends in California revealed that the prevalence of obesity was higher for individuals who did more automobile travel [6]. The relationship between obesity and fuel prices was further investigated by Courtemanche [7], who estimated that a US\$1 increase in real gasoline prices will reduce obesity in the United States by 15% in five years, by increasing exercise due to discouraged automobile use, as well as by decreasing the number of meals eaten at restaurants.

One study has shown the effect of pedestrian-friendly urban planning on obesity rates and automobile use. This study, conducted in King County, Washington, found that both obesity and automobile use were reduced in areas where walking was an effective mode of transportation [8]. The effectiveness of walking is measured by a "walkability index" that depends on residential density, street connectivity, type of land use, and retail floor area ratio. While this study indicates that both obesity and automobile use can be reduced by creating a pedestrian-friendly environment, individuals living in the inner city, where residential density and street connectivity are high, also have a high prevalence of obesity [9], which suggests that the relationship between obesity and the built environment is not a simple one.

In addition to these studies, which establish a correlation between individual travel behavior and obesity, there is also a direct relationship between obesity and fuel consumption. Adding passenger weight to a vehicle tends to degrade fuel economy, thereby increasing fuel consumption. Therefore, increasing obesity among a vehicle's passengers will require additional fuel consumption during travel. This relationship has been explored in the literature in both airline and highway travel. Average weight gain in the United States during the 1990s accounted for 350 million gallons of jet fuel consumed during the year 2000, about

2.4% of the total volume of jet fuel used in domestic service [10], while average weight gain since the 1960s accounts for up to 938 million gallons of the gasoline consumed by cars and light trucks each year [11].

All historical weight gain, however, is not necessarily unhealthy. For example, if weight were only gained by individuals classified as underweight, average weight in the population would increase, but obesity rates would not. In fact, this weight gain would likely reflect an improvement in national health. Furthermore, an adult is considered overweight if their body mass index (BMI) is greater than 25, where BMI is computed by dividing height in meters by the square of weight in kilograms. Between 1960 and 2002, the height of the average adult in the United States increased by approximately one inch [12]; this increase in height should partially offset increasing obesity rates by reducing average BMI.

The goal of this study is to quantify the additional fuel consumption in the United States each year due to passenger overweight and obesity, as well as due to *historical weight gain* in the US population, which is estimated by the change in average weight over a specified time period. Fuel consumed by noncommercial passenger highway vehicles (i.e., cars and light trucks) was considered in the analysis. The analysis is based on the methodology presented by Jacobson and McLay [11], which estimates the fuel consumption that can be attributed to changes in passenger weight. There are four components to this methodology:

1. Average extra weight in the US population is estimated for six combinations of age (2–14 years, 15–19 years, 20–74 years) and gender (male and female).
2. Average extra weight per vehicle passenger is estimated by a probability model that considers the age and gender distribution of vehicle passengers. Different models are used for driving and nondriving passengers.
3. The average extra passenger weight per car and light truck is estimated by combining the average extra weight per passenger with the average number of passengers per vehicle.
4. The amount of fuel consumption attributable to this extra passenger weight is assessed by determining its impact on average fuel economy, which can be translated into the related impact on fuel consumption.

These components will be discussed individually in later sections. The last three components follow directly from the model proposed by Jacobson and McLay [11], while the average extra weight in the US population is assessed using two different methods. The first method estimates extra weight as the historical weight gain in the US population over several time periods, comparing national average weight estimates in 2005–2006 with those dating back as far as the 1960s. This is the method used by Jacobson and McLay [11]; the results of that study are made more current through the use of weight and travel statistics that have been released since its publication. The second method provides a direct estimate for the *average weight attributable to overweight and obesity* in the US population, using the model introduced by Jacobson and King [13]. The carbon emissions due to this additional fuel consumption are computed to quantify how this additional fuel consumption affects the environment.

This paper is organized as follows: The section titled “Data-Sets and Methodology” describes the data used in the analysis. The section titled “Estimating Weight Due to Overweight and Obesity” describes a model for estimating the average weight in the US population that can be attributed to overweight and obesity, which is the second method used to compute average additional weight in the US population in the methodology described above. The section titled “Estimating Fuel Consumption due to Overweight and Obesity” summarizes the Jacobson and McLay [11] model for estimating fuel consumption, which discusses the remaining three components of the methodology. The section titled “Analysis” summarizes the fuel consumption and carbon emission estimated by applying this methodology

to current travel and weight statistics in the United States, as originally reported by Jacobson and King [13], and the section titled “Conclusions” gives the key conclusions of the analysis and discusses further implications of this study and the results reported.

DATA-SETS AND METHODOLOGY

This section summarizes the data used within this study, which fall into three categories: passenger data that describe the age and gender of vehicle passengers, weight data that estimate the weights of these passengers based on those demographics, and vehicle data that estimate the effect of the added weight on national fuel consumption. These data are published by several government agencies, and represent a consistent level of data granularity, aggregating over all people and travel, rather than simulating the travel of each individual person or vehicle. As these data are published by the US government, they are assumed to be reliable. As this study presents fuel consumption estimates that update the results published by Jacobson and McLay [11], this section focuses on the differences between these data, to facilitate comparison between the two studies.

Passenger Data

Passengers are classified according to two demographics: age and gender. According to their ages, passengers are classified as children (0–14 years), teenagers (15–19 years), or adults (20–74 years). Passenger genders can be either male or female. For driving passengers, the distributions over these two demographics are determined by the distribution of licensed drivers in the United States, weighted by the expected daily miles traveled by each gender. Drivers are assumed to be teenagers or adults, with children excluded, leaving four age and gender combinations to consider. The number of licensed drivers in each combination in 2005, as reported by the US Department of Transportation, Federal Highway Administration, is $LD_{M,15-19\text{yrs}} = 4.78 \times 10^6$, $LD_{M,20+\text{yrs}} = 9.55 \times 10^7$, $LD_{F,15-19\text{yrs}} = 4.56 \times 10^6$, and

$LD_{F,20+\text{yrs}} = 9.57 \times 10^7$, where $LD_{G,A}$ is the number of licensed drivers of gender G with age A [14]. When comparing these statistics with the 2003 statistics used by Jacobson and McLay [11], a small increase in the number of teenage drivers is observed (less than 0.5% for each gender), while a larger increase in the number of adult drivers is observed (more than 2% for each gender). As such, the average driver is more likely to be an adult (as opposed to a teenager) in 2005 than in 2003. The US Department of Transportation, Bureau of Transportation Statistics [15], has estimated that males travel 37.6 miles per day in automobiles, while females travel 21.2 miles per day. These data are the same as those used by Jacobson and McLay [11], as new data have not been released.

The ages and genders of nondriving passengers are more difficult to estimate, as there is no reliable model to estimate their distribution. Therefore, following from Jacobson and McLay [11], several different cases are considered for these distributions:

- *Case 1.* The distribution of a nondriving passenger’s age and gender is identical to the distribution for the driver.
- *Case 2.* The distribution of a nondriving passenger’s age and gender follows the distribution defined by the US population demographics, as estimated for 2006 by the United States Census Bureau [16].
- *Case 3.* All nondriving passengers are children or teenagers (age 0–19 years).

In the first case, passengers cannot be children (who tend to weigh less than teenagers or adults) and are more likely to be males (who tend to weigh more than females); therefore, this case establishes an upper bound on passenger weight. In contrast, the third case prevents passengers from being adults, who tend to weigh more than children or teenagers; this case establishes a lower bound on passenger weight. In the second case, all ages are represented, according to the age and gender distribution established by the most recent US census, as estimated for the year 2006 [16]. The marginal distributions for

both age and gender are estimated by the proportion of individuals in each gender or age classification. The estimated age distribution is $P(0-14 \text{ yrs}) = 0.203$, $P(15-19 \text{ yrs}) = 0.071$, and $P(20-74 \text{ yrs}) = 0.726$. The gender distribution is $P(M) = 0.493$ and $P(F) = 0.507$. Passenger weight computations for each case are discussed in the section titled "Passenger Weight Computations," where they are scaled by the number of passengers per vehicle to estimate the total passenger weight in a vehicle.

This model of passenger demographics does not account for any trends other than age or gender. As such, this model assumes that no relationships between vehicle use and other demographics exist. For example, it must be assumed that an individual's travel behavior is independent of their weight; that is, two passengers with the same gender and age classifications will exhibit identical travel patterns, regardless of their weight classification. Similarly, it is assumed that the average weight of an individual passenger is the same, on average, for both cars and light trucks. As there are no robust national statistics that contradict these assumptions, they are assumed to be reasonable. However, at least one regional survey [6] has suggested a positive correlation between automobile use and obesity; if such a correlation does exist, then the fuel consumption estimates presented in this paper will tend to underestimate the additional passenger weight present in vehicles, making these estimates conservative lower bounds.

Weight Data

Weight data describe the average weight of individuals in the US population, given their age and gender demographics; when used in conjunction with the passenger data described in section titled "Passenger Data," these data can be used to compute the average weight of a vehicle passenger. Weight data are based on the results of the National Health and Nutrition Examination Survey (NHANES) for the years 2005–2006, which is conducted by the National Center for Health Statistics [17]. Every two years, the NHANES distributes survey data collected from approximately 10,000 participants;

roughly half of these participants being examined each year after being chosen from one of 15 designated counties [18]. To allow national statistics to be generated from the survey results, the NHANES uses a multistage probability model to choose participants [19]. A sample weight measuring the number of people in the US population that are represented by each participant is assigned based on the sampling process and nonresponse rates [20]. These sample weights should not be confused with the physical body weight associated with each participant; in this paper, the term *sample weight* will be used when referring to the sample weights assigned during the NHANES. All height and weight measurements in the NHANES are taken directly, rather than self-reported, to ensure that their values are accurate. Individuals tend to underestimate their weight and overestimate their height during self-report [21,22], which leads to inaccurate BMI computations and, consequently, inaccurate assessment of overweight and obesity; the direct measurement of these quantities in the NHANES avoids this bias.

While a total of 10,348 individuals participated in NHANES 2005–2006, some of these individuals are excluded from the analysis conducted for this study. A participant was excluded if their BMI could not be accurately assessed. Some participants did not have their height or weight measured; for example, no height measurements were taken for children younger than the age of two. In other cases, the height or weight measurements do not accurately reflect a person's true height or weight; an individual is excluded from analysis if their height was not measured at full standing, or if their weight measurement included a medical appliance. Pregnant women were not excluded from analysis. After excluding these individuals, 8678 participants remained and were used to compute weight estimates.

Average weight estimates for individuals in each age and gender combination are shown in Table 1. These average weights differ from those used by Jacobson and McLay [11], which were based on NHANES 1999–2002. During the time between these two studies, it is estimated that the average

Table 1. Average Weight (lbs) by Age and Gender, Including Reduced Weight Classifications, 2005–2006

Weight Classification Reduced	Age (years)	Weight ^a (Male)	Weight ^a (Female)
None	2–14	76.4	75.9
	15–19	167	142
	20–74	197	167
Overweight, obese, and extremely obese	2–14	73.6	72.9
	15–19	159	137
	20–74	168	139
Overweight only	20–74	190	163
Obese only	20–74	180	152
Extremely obese only	20–74	191	158

^a 1 lb = 0.4536 kg.

weight of an adult male has increased by six pounds (191–197 lbs), the average weight of male teenagers and female adults have each increased by three pounds (164–167 lbs), and the average weight of a female teenager has increased by two pounds (140–142 lbs). Based on these estimates, national weights have continued to increase between the completion of NHANES 1999–2002 and the completion of NHANES 2005–2006. As noted earlier, some of the increase in average weight may not be due to additional overweight and obesity, as these classifications are affected by changes in height.

To assess the amount of fuel consumption that can be attributed to extra passenger weight, the amount of such weight must be quantified. Table 1 includes average weight estimates for each age and gender combination if weight due to overweight, obesity, and/or extreme obesity were eliminated. The methodology used to generate these estimates is discussed in the section titled “Estimating Weight due to Overweight and Obesity.” Given these estimates, one method for assessing extra passenger weight is to determine the average weight that can be attributed to overweight and obesity in the US population; this value can be computed from the contents of Table 1. Alternatively, extra passenger weight can be found by comparing the current weight estimates (i.e., those with no weight classification reduced)

in Table 1 with average weight estimates from previous years to quantify historical weight gain over specific time periods; this methodology was used by Jacobson and McLay [11].

Vehicle Data

Once the extra passenger weight has been computed, vehicle data are used to assess the effect that this change in weight exerts on fuel consumption. To carry out this analysis, vehicle data are gathered. These data measure the use and performance of vehicles in each fleet being considered (i.e., cars and light trucks), as well as the sensitivity of vehicle performance to changes in weight. In this vein, four parameters are collected to reflect the current use and performance of each fleet of vehicles: annual vehicle miles traveled, annual passenger miles traveled, annual fuel consumption, and number of registered vehicles. This study collects these parameters for travel in 2005 [2], while Jacobson and McLay [11] consider travel in 2003 (Table 2). Between 2003 and 2005, fuel consumption has risen at a faster rate than vehicle miles traveled for light trucks, reflecting a decline in average fuel economy. In contrast, vehicle miles traveled for cars have increased, while fuel consumption has declined, reflecting an improvement in fuel economy.

Adding weight to a vehicle tends to degrade the vehicle’s fuel economy. A fifth parameter, reflecting this relationship, is reported by the US Environmental Protection Agency [23] for cars in model year (MY) 2007. This parameter measures the linear change in fuel consumption (measured as the number of gallons required to travel one hundred vehicle miles) caused by a one pound increase in vehicle weight. Hybrid and diesel vehicles are excluded from these estimates. The estimated slopes are 8.78×10^{-4} gal/100 miles/lb for cars and 8.95×10^{-4} gal/100 miles/lb for light trucks (1 gal/100 miles/lb = 5.186 L/100 km/kg). In contrast, Jacobson and McLay [11] use data based on the model year 2005, where these slopes are 7.27×10^{-4} gal/100 miles/lb for cars and 1.16×10^{-3} gal/100 miles/lb for light trucks. Between 2005 and 2007, fuel consumption in cars has become more sensitive

Table 2. Vehicle Use Statistics, Given Vehicle Type, 2003–2005

Quantity	Units	Cars		Trucks	
		2003	2005	2003	2005
Vehicle miles	miles ^a	1661 B	1690 B	998 B	1060 B
Passenger miles	miles ^a	2624 B	2670 B	1730 B	1837 B

Number registered vehicles	—	136 M	137 M	87.0 M	95.3 M

^a 1 mile = 1.609 km.^b 1 gallon = 3.785 L.

to changes in weight, while fuel consumption in light trucks has become less sensitive.

ESTIMATING WEIGHT DUE TO OVERWEIGHT AND OBESITY

The first component of the fuel consumption model describes the estimation of the average extra weight in the US population. While this extra weight is evaluated as historical weight gain, for example, by comparing current national weight statistics to those from the 1960s [12] by Jacobson and McLay [11], it can also be quantified by considering the average weight loss required to eliminate overweight and obesity in the current US population. As discussed earlier, all historical weight gain is not necessarily unhealthy. By quantifying the passenger weight due to overweight and obesity, the resulting fuel consumption estimates are solely attributable to weight that is considered unhealthy. One method for computing such weight statistics, first introduced by Jacobson and King [13], is presented in this section. Rather than using the NHANES data directly, these data are altered such that each participant classified as overweight or obese is reduced to their *maximum normal weight*, or the weight at which the individual achieves the highest possible BMI to be classified as normal weight. Average weight statistics can be computed from these altered data and compared to weight statistics generated by the unaltered NHANES data to determine the average weight attributable to overweight and obesity in the United States, which can take the role of average extra weight in the model described by Jacobson and McLay [11].

Weight Classifications

To compute a person's maximum normal weight, a system of weight classifications must be established. These classifications are based on BMI, and differ by age. An adult can be considered underweight ($\text{BMI} < 18.5$), normal weight ($18.5 \leq \text{BMI} < 25$), overweight ($25 \leq \text{BMI} < 30$), obese ($30 \leq \text{BMI} < 40$), or extremely obese ($\text{BMI} \geq 40$); therefore, the maximum normal weight for an adult occurs when BMI is equal to 25 [3]. For children below 20 years of age, overweight status is determined by the BMI-for-age growth charts for boys and girls, as established by the Centers for Disease Control and Prevention [24]. A child is classified as overweight if their BMI is greater than the 95th percentile of BMI for their age. This cutoff is at its minimum at age four—when it is 17.8 for males and 18.0 for females—and at its maximum at age 19—when it is 30.6 for males and 31.8 for females.

Computing Weight Estimates

In order to eliminate overweight and obesity in the US population, all individuals must be reduced to their maximum normal weight. This will occur when each individual experiences a weight loss of

$$\text{WL} = \max\{W - \text{BMI}_N H^2, 0\}, \quad (1)$$

where BMI_N is the maximum BMI in the normal range (25 for adults, varies according to age for teenagers and children), and W and H are the individual's weight and height, respectively. No weight is lost if the individual is already of normal weight (or underweight); their weight loss is equal to zero.

The sample weights associated with the NHANES can be used to compute average weight statistics after these weight losses are applied. To compute the statistics for a particular age and gender classification, let J be the set of all survey participants that meet the age and gender requirements. For any particular individual, j , their sample weight, sw_j , determines the number of people in the US population that are represented by person j . Therefore, the average weight for individuals with this age and gender classification is computed as

$$W_A' = \frac{\sum_{j \in J} sw_j (W_j - WL_j)}{\sum_{j \in J} sw_j}, \quad (2)$$

where W_j is the weight of individual j , and WL_j is the weight loss for individual j , as computed in Equation (1).

Average weight estimates generated by this methodology are reported in Table 1. Four alternative cases are presented, each applying the weight loss computed in Equation (1) to a different set of surveyed individuals. In the first case, weight loss is applied to individuals classified as overweight, obese, or extremely obese. The remaining three cases apply weight loss to only one of the three classifications (e.g., weight loss is only applied to individuals classified as overweight). Since children and teenagers are not classified as obese or extremely obese, their average weights are omitted when weight loss is only applied to individuals with those classifications.

Table 1 shows that, for example, the average weight for an adult male falls from 197 to 168 lbs if weight loss is applied to overweight, obese, and extremely obese individuals, while it falls from 197 to 180 lbs if weight loss is only applied to obese individuals. Of the weight loss that results from eliminating overweight, obesity, and extreme obesity, some can be attributed to the weight loss in each classification.

In adult (age 20–74 years) females, prevalence of overweight is 25%, prevalence of obesity is 29%, and prevalence of extreme obesity is 7%. From Table 1, 13% of total

weight loss is due to individuals classified as overweight, 54% is due to individuals classified as obese, and 33% is due to individuals classified as extremely obese. Though a small fraction of adult females are classified as extremely obese, approximately one-third of the total weight loss is due to extreme obesity, reflecting the larger weight loss experienced by individuals classified as extremely obese. However, the majority of total weight loss is due to individuals who are classified as obese, reflecting the larger weight loss and higher prevalence of individuals classified as obese.

The prevalence of overweight in adult males is approximately 40%, while obesity has 30% prevalence and extreme obesity has 4% prevalence. However, from Table 1, 23% of total weight loss is due to individuals who are classified as overweight, 56% is due to individuals classified as obese, and 21% is due to individuals classified as extremely obese. Though obesity is less prevalent than overweight, an obese individual tends to experience more weight loss than an overweight individual, so more of the total weight loss is due to the reduction of obesity. Extreme obesity is much less prevalent, so less of the total weight loss is due to individuals who are extremely obese.

ESTIMATING FUEL CONSUMPTION DUE TO OVERWEIGHT AND OBESITY

Once average extra weight in the US population has been estimated, the impact of this weight change on fuel consumption can be assessed. First, the average extra weight of driving and nondriving vehicle passengers must be computed by determining the age and gender distributions of these passengers, in conjunction with the average extra weight of each age and gender combination. Second, the average extra passenger weight per vehicle is determined by scaling the average extra weight of each passenger type by the average number of passengers in each vehicle. These two tasks represent the second and third components of the fuel consumption model (discussed in the section titled “Passenger Weight Computations”). Finally, the fourth component of the fuel

consumption model assesses the effect of the average extra weight on fuel economy, which is then translated into a change in fuel consumption (discussed in the section titled “Fuel Economy Computations”).

Passenger Weight Computations

The age and gender demographics of each passenger are used to determine the weight of that passenger. Passengers can be either driving or nondriving passengers, whose weight and demographic data are given a subscript of D and ND, respectively. Clearly, the same demographic distributions cannot be used for both driving and nondriving passengers. For example, nondriving passengers can be children, while driving passengers can only be teenagers or adults. Therefore, the total passenger weight in a vehicle from fleet V is computed as

$$E[W_V] = E[W_D] + (N_V - 1)E[W_{ND}], \quad (3)$$

where $E[W_D]$ and $E[W_{ND}]$ are the average weights of driving and nondriving passengers, and N_V is the average number of passengers in vehicles from fleet V. An estimate for N_V is computed as passenger miles traveled by vehicles in the fleet, divided by vehicle miles traveled by those vehicles. Passenger weights are computed by the conditional expectations

$$E[W_D] = \sum_{A_D, G_D} E[W_D | A_D \cap G_D] \times P(A_D | G_D) P(G_D), \quad (4)$$

$$E[W_{ND}] = \sum_{A_{ND}, G_{ND}} E[W_{ND} | A_{ND} \cap G_{ND}] \times P(A_{ND} | G_{ND}) P(G_{ND}). \quad (5)$$

For both driving and nondriving passengers, average passenger weight given age and gender demographics is assumed to be equal to the average weight for a person in those same demographics in the entire US population, as reported in Table 1. Therefore,

$$\begin{aligned} E[W_D | A_D \cap G_D] &= E[W_{ND} | A_{ND} \cap G_{ND}] \\ &= E[W | A \cap G]. \end{aligned} \quad (6)$$

Given this assumption, the only difference between driving and nondriving passengers lies in their age and gender distributions. The data used to estimate these distributions were reported in the section titled “Passenger Data.”

For driving passengers, age and gender are determined by the distribution of licensed drivers in the United States, as well as the daily miles traveled by each gender. Children cannot be drivers; all drivers must be teenagers or adults. Given the driver’s gender (G_D), their age (A_D) follows a distribution that is defined by the proportion of licensed drivers in each age classification

$$P(A_D | G_D) = LD_{G_D, A_D} / \sum_A LD_{G_D, A}, \quad (7)$$

where $LD_{G,A}$ is the number of licensed drivers with gender G and age A . The gender distribution for drivers is defined by the proportion of miles driven by each gender

$$P(G_D) = \frac{E[DM|G_D] \sum_A LD_{G_D, A}}{\sum_G E[DM|G] \sum_A LD_{G, A}}, \quad (8)$$

where $E[DM|G]$ is the daily miles driven by individuals with gender G .

The distributions of age and gender for nondriving passengers are defined differently for each passenger case, as described in the section titled “Passenger Data.” For Case 1, these distributions are the same as those for driving passengers, so $P(A_{ND}|G_{ND}) = P(A_D|G_D)$ and $P(G_{ND}) = P(G_D)$. For Case 2, these distributions are defined by estimates from the US Census for the year 2006 [16]. In this case, age and gender are assumed to be independent variables, such that $P(A_{ND}|G_{ND}) = P(A_{ND})$. These probabilities are defined by the proportion of individuals in each age and gender classification in the census data, as described in the section titled “Passenger Data.”

For Case 3, passengers must be children and teenagers. Census data and daily miles

traveled by each gender define the age and gender distributions. Let $A' = \{0-14 \text{ years}, 15-19 \text{ years}\}$ be the set of age classifications for children and teenagers. The gender, G' , of a nondriving passenger for Case 3 is given by the weighted average

$$P(G') = \frac{E[DM | G'] \sum_{A \in A'} P(G', A)}{\sum_G \left(E[DM | G] \sum_{A \in A'} P(G, A) \right)}, \quad (9)$$

where $P(G, A) = P(G)P(A)$, and the proportion of individuals of each gender and age classification are computed using US Census estimates for 2006 [16]. The average weight of a nondriving passenger of gender G' is given by

$$\begin{aligned} & E[W_{ND} | G'] \\ &= \frac{\sum_{A \in A'} E[W_{ND} | A_{ND} \cap G_{ND}] P(G', A)}{\sum_{A \in A'} P(G', A)}. \end{aligned} \quad (10)$$

Therefore, the average weight of a non-driving passenger in Case 3 is computed as

$$E[W_{ND}] = E[W_{ND} | M] P(M) + E[W_{ND} | F] P(F), \quad (11)$$

rather than using Equation (5), where M and F reflect the case when the gender is male and female, respectively.

Fuel Economy Computations

In general, the fuel economy of a vehicle improves when the vehicle carries less weight. For a fleet of vehicles, V , let the average extra passenger weight per vehicle be given by ΔW_V . This extra weight is computed as historical weight gain or average weight attributable to overweight and obesity in the US population. Fuel economy is defined as the number of miles that a vehicle travels when consuming one gallon of gasoline; alternatively, it is the inverse of the number of gallons required to travel one

mile. Using this alternative formulation, the inverse of fuel economy falls by $\Delta W_V R_V / 100$ when passenger weight is decreased by ΔW_V (i.e., the average extra passenger weight per vehicle is removed), since $R_V / 100$ measures the number of additional gallons required to travel one vehicle mile caused by a one pound increase in vehicle weight. Therefore, if FE_V is the current fuel economy for vehicles in fleet V , this decrease in passenger weight causes fuel economy to increase to

$$FE_V' = [1/FE_V - \Delta W_V R_V / 100]^{-1}, \quad (12)$$

and fuel consumption decreases to

$$FC_V' = VM_V / FE_V', \quad (13)$$

where VM_V measures the vehicle miles traveled by fleet V . The fuel consumption estimates computed with this model can be compared with the fuel consumption for 2005, as reported in Table 2.

ANALYSIS

This paper estimates the annual additional fuel consumption for cars and light trucks in the United States due to the average extra passenger weight carried by cars and light trucks. This extra weight is estimated in two ways, both comparing current weights statistics computed from NHANES 2005–2006 with alternative weight cases. First, average extra weight is estimated by historical weight gain in the US population over several past time periods. Time periods considered in this study are 1960–1962, 1971–1974, 1976–1980, 1988–1994, and 1999–2002. Second, average extra weight is computed by assessing the weight loss that would be required to eliminate overweight, obesity, extreme obesity, or all three, from the US population. These weight estimates are computed using the methodology of section titled “Estimating Weight due to Overweight and Obesity.” Other than passenger weight, all data are held constant in the analysis.

Using the vehicle data described in the section titled “Vehicle Data,” several statistics can be computed. The average number of

passengers in a vehicle in fleet V is estimated as the passenger miles traveled divided by vehicle miles traveled. On average, each car holds 1.58 passengers, while each light truck carries 1.73 passengers. These values are indistinguishable from the values computed by Jacobson and McLay [11], which suggests that ridesharing patterns, on average, have not changed substantially between 2003 and 2005. Average fuel economy for vehicles in fleet V is estimated as vehicle miles divided by fuel consumed. Average fuel economy for cars is estimated as 22.9 miles per gallon (mpg), reflecting an improvement of 0.6 mpg from the estimate made by Jacobson and McLay [11]. Average fuel economy for light trucks is estimated as 16.2 mpg, which is 1.5 mpg less than the estimate made by Jacobson and McLay [11].

Additional Fuel Consumption Due to Historical Weight Gain

When average extra weight is estimated by historical weight gain, the estimated annual additional fuel consumption, as first reported by Jacobson and King [13], is reported in Table 3. To aid comparison, the results

reported by Jacobson and McLay [11] are also given. When comparisons are made in a single column, only changes in weight data between time periods are reflected. For example, the first column reports annual fuel consumption when weight estimates from 1999–2002 are compared to those in previous time periods (e.g., 1976–1980) using vehicle and passenger data from 2003. Since the two columns use vehicle and passenger data from different years, comparisons made between the two columns also reflect these differences. For example, consider the 1988–1994 row, for passenger Case 1. The first column reports that 357 million gallons of fuel are consumed each year according to historical weight gain between 1988–1994 and 1999–2002 in conjunction with passenger and vehicle data from 2003. The second column reports that 545 million gallons of fuel are consumed each year due to historical weight gain between 1988–1994 and 2005–2006 in conjunction with passenger vehicle data from 2005. Therefore, the 52.8% change observed between these two estimates incorporates not only historical weight gain between 1999–2002 and 2005–2006, but also changes in passenger and vehicle

Table 3. Additional Gallons of Fuel Consumed Annually Due to Historical Weight Gain in the US Population Over Several Time Periods

Time Period	Case	Additional Fuel (gallons ^a), When Compared to		% Change

^c Historical weight gain found by comparing weight statistics in 2005–2006 with those in the specified time period, using passenger and vehicle data from 2005 [13].

Table 4. Estimated Annual Fuel Savings (Gallons) by Reducing Weight of Overweight, Obese, or Extremely Obese Individuals to Maximum Normal Weight BMI

Weight Classification Reduced	Additional Fuel (Gallons ^a)		
	Case 1	Case 2	Case 3
Overweight only	223M	209M	196M
Obese only	608M	549M	371M
Extremely obese only	273M	252M	166M
Overweight, obese, and extremely obese	1104M	1011M	734M

^a1 gallon = 3.785 L; sums may differ due to independent rounding.

data between 2003 and 2005. The largest annual additional fuel consumption is 1.137 billion gallons, according to historical weight gain since the 1960s when all passengers are adults and teenagers. This amount of fuel accounts for 0.8% of the gasoline consumed by cars and light trucks in 2005 [2].

According to this model, between 182 and 199 million additional gallons of fuel can be attributed to historical weight gain since 2002; by subtracting from 1.137 billion gallons, this computation indicates that 938–955 million additional gallons can be attributed to historical weight gain between 1960 and 2002, which is comparable to the 938 million gallon estimate that was reported by Jacobson and McLay [11]. If each passenger were to gain one pound, this model estimates that an additional 39.8 million gallons of fuel would be consumed each year, a small increase from the estimate of 39.2 million gallons reported by Jacobson and McLay [11].

Each gallon of gasoline consumption causes 19.4 pounds (8.80 kg) of carbon dioxide (CO₂) emissions [25]. Therefore, the 1.137 billion gallons of fuel consumed due to historical weight gain since the 1960s leads to 22.1 billion pounds (10.0 million metric tons) of CO₂ emissions, accounting for 0.5% of the total CO₂ emissions produced by combusting fossil fuels for use in the transportation sector in 2005 [26].

Projected Fuel Savings by Reducing Overweight and Obesity

When average extra weight is estimated by the average weight attributable to

overweight and obesity, the estimated annual additional fuel consumption is reported in Table 4. If overweight, obesity, and extreme obesity were eliminated from the US population, between 734 million and 1.104 billion gallons of fuel would be saved each year. This savings can be stratified by weight classification; regardless of which passenger case is used, more than half of the total savings is due to individuals classified as obese. This result is consistent with the earlier observation that more than half of the weight lost by eliminating overweight, obesity, and extreme obesity in adults would be due to the elimination of obesity. Furthermore, all passengers in Case 3 must be children and teenagers, for whom no classification of obesity or extreme obesity exists. Therefore, all fuel savings due to elimination of obesity and extreme obesity must be the average extra weight of the driver, which accounts for more than 73% of the total fuel saved.

Using these estimates of potential fuel savings, the 1.104 billion gallons of fuel that could be saved by eliminating overweight and obesity would also eliminate 21.4 billion pounds (9.71 million metric tons) of CO₂ emissions, or 0.5% of the total CO₂ emissions produced by combusting fossil fuels for use in the transportation sector in 2005 [26].

CONCLUSIONS

This paper quantifies the additional amount of fuel consumed each year due to average extra passenger weight in noncommercial passenger highway vehicles (i.e., cars and light trucks). Two scenarios are considered: in the first scenario, average extra passenger weight is based on historical weight gain in the US population over several past time periods, and in the second scenario, average extra passenger weight is computed as the average weight attributable to overweight and obesity in the US population. Regardless of which scenario is chosen, up to one billion gallons of fuel or more are found to be attributable to extra passenger weight. In the first scenario, if average extra weight is based on historical weight gain since the 1960s, estimates reach as high as 1.137 billion gallons,

while the second scenario generates estimates of up to 1.104 billion gallons. Both estimates represent approximately 0.8% of the fuel consumed by cars and light trucks each year, and consuming this additional fuel produces up to 0.5% of the CO₂ emissions generated by combusting fossil fuels in the transportation sector in 2005. Though these estimates represent a very small fraction of the total fuel consumption and CO₂ emissions produced annually in the United States, the estimates are large in absolute terms.

These estimates may change over time, particularly as travelers in the United States react to record gasoline prices. It has been estimated that a US\$1 increase in real gasoline prices will reduce obesity in the United States by 15% over five years by discouraging automobile use and decreasing the number of meals eaten at restaurants [7]. Such a result would not only decrease the vehicle miles traveled by cars and light trucks, but would also decrease the weight of passengers carried by those vehicles, both of which would reduce fuel consumption.

Fuel savings can also be realized in other ways. For example, the amount of fuel that could be saved by maintaining proper tire inflation was estimated to be 1.388 billion gallons each year, slightly more than the fuel consumption attributable to overweight and obesity [27]. Fuel can also be saved by ridesharing (i.e., carpooling). If one additional passenger were added to every hundred vehicles (cars and light trucks) without needing to be picked up, the annual fuel savings could be as high as 0.82 billion gallons [28]. Individually, these initiatives make up a small portion of the gasoline consumed in the United States, but each highlights an opportunity to reduce the high level of national oil consumption.

The results in this paper quantify the impact of obesity on fuel consumption. However, the reverse relationship may also be true. In particular, as fuel consumption has increased, so have obesity rates. This begs the question: If fuel consumption levels drop, will obesity rates follow? Lopez-Zetina *et al.* [6] report a positive relationship between time spent in a car and obesity rates in

California. It has been suggested that the recent surge in overweight and obesity rates in China correlates with an increased level of automobile ownership [29], indicating that the issues being faced by the United States will become international issues as nations become more affluent. From a practical point of view, every trip that replaces automobile use with walking, riding a bicycle, or using public transit requires a greater physical exertion of energy, and hence will lead to a weight reduction.

From a broad perspective, the model presented in this paper shows how mathematical modeling and operations research can quantify the direct relationship that exists between two seemingly unrelated issues. As this model is driven by national statistics, the use of data that control for the age and gender of driving and nondriving passengers provides a more accurate estimate of average extra passenger weight, and hence the additional fuel consumption due to this weight.

These national estimates are hindered by the dearth of data that describe how driving habits depend on factors such as income, race, and weight. Therefore, the model does not control for these factors and assumes that a passenger's income, race, and weight do not shape their driving habits. While these factors undoubtedly exert some level of influence, the degree of this influence is not clear. If estimates of how these demographics affect travel behavior could be quantified, they could be used to improve the estimation of passenger weight and further increase the accuracy of the fuel consumption estimates generated by this model. If a strong connection exists between these demographics and driving habits, then the fuel consumption estimates presented here may differ substantially from those generated by a more robust model that included these factors. If data that could support such a model become available in the future, the results presented in this paper should be reevaluated. In addition, the estimates presented in this paper estimate the fuel consumption due to overweight and obesity in the current national vehicle fleet. As the nature of the vehicle fleet changes (e.g., changes in the number of

larger vehicles such as SUVs, or the number of hybrid vehicles), the fleet's reaction to changes in passenger weight due to overweight and obesity will fluctuate. Therefore, the fuel consumption estimates presented here can be expected to change over time.

Quantifying the relationship between the socioeconomic issues of fuel consumption and obesity is valuable to both energy and public health policymakers, as it allows them to consider an additional benefit of public health initiatives that aim to reduce obesity in the US population. While the main economic impact of such initiatives would be a reduction in annual health-care expenditures associated with overweight and obesity, which were estimated to have been \$78.5 billion in 1998, accounting for 9.1% of all medical expenditures in the United States [30], the additional benefit of savings up to a billion gallons of fuel each year provides another significant and measurable benefit.

A STRUCTURAL CLUSTERING ALGORITHM FOR LARGE NETWORKS

XIAOWEI XU

Arkansas

INTRODUCTION

Networks are ubiquitous. Common networks include social networks, the World Wide Web, and computer networks. A network consists of a set of vertices interconnected by edges. A vertex represents some real entities such as a person, website, or piece of networking hardware. An edge connects two vertices if they have some relationship such as a friendship, hypertext link, or wired connection. In such networks, each vertex plays a role. Some vertices are members of clusters; a group of peers in a social network or a group of related websites in the WWW are examples. Some vertices are hubs that bridge many clusters but do not belong strongly to any one cluster; for example, politicians tend to play such a role in social networks, and websites like wikipedia.org are clearing-houses for all kinds of information. Some vertices represent outsiders that have only weak associations with any cluster; for example, a loner in a social network, or a parked domain on the internet.

To illustrate these points further, consider the network in Fig. 1. If one might confidently consider the vertices $\{0, 1, 2, 3, 4, 5\}$ and $\{7, 8, 9, 10, 11, 12\}$ to be clusters of peers, vertex 6 is difficult to classify. It could arguably belong to either cluster or to none. It is an example of a hub. Likewise, vertex 13 is weakly connected to a cluster. It is an example of an outsider.

Network clustering (or graph partitioning) is the detection of structures like those in Fig. 1, and it is drawing increased attention and application in computer science [1,2], physics [3], and bioinformatics [4]. Various such methods have been developed. They

tend to partition based on the principle that clusters should be sparsely connected, but the vertices within each cluster should be densely connected. Modularity-based algorithms [3–5] and normalized cut [1,2] are successful examples. However, they do not distinguish the roles of vertices.

The modularity-based algorithm [5] will cluster the network in Fig. 1 into two clusters: one consisting of vertices 0 to 6 and the other consisting of vertices 7 to 13. It does not isolate vertex 6 or vertex 13.

The identification of hubs gives valuable information. For example, hubs in the WWW are deemed authoritative information sources among web pages [6], and hubs in social networks are believed to play a crucial role in viral marketing [7] and epidemiology [8].

In this article, we propose a new method for network clustering. The goal of our method is to find clusters, hubs, and outsiders in large networks. To achieve this goal, we use the neighborhood of the vertices as clustering criteria instead of only their direct connections. Vertices are clustered by how they share neighbors. Doing so makes sense when you consider the detection of communities in large social networks. Two people who share many friends should be clustered in the same community.

Referring to Fig. 1, consider vertices 0 and 5, which are connected by an edge. Their neighborhoods are the vertex sets $\{0, 1, 4, 5, 6\}$ and $\{0, 1, 2, 3, 4, 5\}$, respectively. They share many neighbors and are thus reasonably clustered together. In contrast, consider the neighborhoods of vertex 13 and vertex 9. These two vertices are connected, but share only few common neighbors, that is, $\{9, 13\}$. Therefore, it is doubtful whether they should be grouped together. The situation for vertex 6 is a little different. It has many neighbors, but they are sparsely interconnected.

Our algorithm identifies two clusters, $\{0, 1, 2, 3, 4, 5\}$ and $\{7, 8, 9, 10, 11, 12\}$, and isolates vertex 13 as an outsider and vertex 6 as a hub.

Figure 1. A network with two clusters, a hub, and an outsider.

Our algorithm has the following features:

- It detects clusters, hubs, and outsiders by using the structure and the connectivity of the vertices as clustering criteria.
- It is efficient. It clusters the given network by visiting each vertex exactly once.

Through theoretical analysis and experimental evaluation we demonstrate that our algorithm finds meaningful clusters and identifies hubs and outsiders in very large networks.

With respect to efficiency, our algorithm’s running time on a network with n vertices and m edges is $O(m)$. In contrast, the running time of the fast modularity-based algorithm [5] is $O(md \log n)$.

The article is organized as follows. We formalize the notion of structure-connected cluster (SCC) in the section titled “The Notion of Structure-Connected Cluster.” We devise an algorithm to find SCC in the section titled “Algorithm.” We give a computation complexity analysis of our algorithm in the section titled “Complexity Analysis.” We compare our algorithm to the fast modularity-based algorithm in the section titled “Evaluation.” We review the related work in the section titled “Related Work.” Finally, we present our conclusions and suggest future work in the final section.

THE NOTION OF STRUCTURE-CONNECTED CLUSTER

Our goal is both to cluster network optimally and to identify and isolate hubs and outsiders. Therefore, both connectivity and local structure are used in our definition of optimal clustering. In this section, we formalize the notion of a structure-connected cluster that extends that of a density-based cluster [9] and can distinguish clusters, hubs, and outsiders in networks.

The existing network clustering methods such as modularity-based algorithms are designed to find optimal clusters based on the number of edges between vertices or between clusters. Direct connections are important, but they represent only one aspect of the network structure. The neighborhood around two connected vertices is also important. The neighborhood of a vertex includes all the vertices connected to it by an edge. When you consider a pair of connected vertices, their combined neighborhood reveals neighbors common to both.

Our method is based on common neighbors. Two vertices are assigned to a cluster according to how they share neighbors. This makes sense when you consider social communities. People who share many friends create a community, and the more friends they have in common, the more intimate the community. But in social networks there are different kinds

of actors besides peers. There are also people who are outsiders (like hermits), and there are people who are friendly with many communities but belong to none (like politicians). The latter play a special role in small-world networks known as *hubs* [10]. An outsider is illustrated by vertex 13 in Fig. 1 and a hub is illustrated by vertex 6.

In this article, we focus on simple, undirected, and unweighted graph. Let $G = \{V, E\}$ be a graph representing a real network, where V is a set of vertices and E is a set of pairs (unordered) of distinct vertices, called *edges*.

The structure of a vertex can be described by its neighborhood. A formal definition of vertex structure is given as follows.

Definition 1 [Vertex Structure]. Let $v \in V$. The structure of v is defined by its neighborhood, denoted by $\Gamma(v)$:

$$\Gamma(v) = \{w \in V | (v, w) \in E\} \cup \{v\}$$

In Fig. 1, vertex 6 is a hub sharing neighbors with two clusters. If we only use the number of shared neighbors, vertex 6 will be clustered into either of the clusters or cause the two clusters to merge. Therefore, we normalize the number of common neighbors in different ways, which give us different similarity measures.

Definition 2 [Structural Similarity].

$$\sigma_{\cos}(v, w) = \frac{|\Gamma(v) \cap \Gamma(w)|}{\sqrt{|\Gamma(v)| |\Gamma(w)|}} \quad (1)$$

$$\sigma_{\text{jaccard}}(v, w) = \frac{|\Gamma(v) \cap \Gamma(w)|}{|\Gamma(v) \cup \Gamma(w)|} \quad (2)$$

$$\sigma_{\min}(v, w) = \frac{|\Gamma(v) \cap \Gamma(w)|}{\min(|\Gamma(v)|, |\Gamma(w)|)}. \quad (3)$$

The first similarity, called *cosine similarity*, normalizes the number of common neighbors by the geometric mean of the two neighborhoods' size and is commonly used for information retrieval. The second similarity, called *Jaccard similarity*, normalizes the number of common neighbors by the arithmetic mean

of the two neighborhoods' size. The third similarity, called *min similarity*, normalizes the number of common neighbors by the minimum of the two neighborhoods' size. In the section titled "Evaluation," we compare the similarities with respect to the clustering accuracy.

When a member of a cluster shares a similar structure with one of its neighbors, their computed structural similarity will be large. We apply a threshold ε to the computed structural similarity when assigning cluster membership, formulized in the following ε -neighborhood definition.

Definition 3 [ε -Neighborhood].

$$N_{\varepsilon}(v) = \{w \in \Gamma(v) | \sigma(v, w) \geq \varepsilon\}.$$

When a vertex shares structural similarity with enough neighbors, it becomes a nucleus or *seed* for a cluster. Such a vertex is called a *core vertex*. Core vertices are a special class of vertices that have a minimum of μ neighbors with a structural similarity that exceeds the threshold ε . From core vertices we grow the clusters. In this way the parameters μ and ε determine the clustering of the network. For a given ε , the minimal size of a cluster is determined by μ .

Definition 4 [Core]. Let $\varepsilon \in \mathbb{R}$ and $\mu \in \mathbb{N}$. A vertex $v \in V$ is called a core with respect to ε and μ , if its ε -neighborhood contains at least μ vertices, formally:

$$CORE_{\varepsilon, \mu}(v) \Leftrightarrow |N_{\varepsilon}(v)| \geq \mu.$$

We grow clusters from core vertices as follows. If a vertex is in ε -neighborhood of a core, it should also be in the same cluster because they share a similar structure and are connected. This idea is formulized in the following definition of direct structure reachability.

Definition 5 [Direct Structure Reachability].

$$\begin{aligned} DirREACH_{\varepsilon, \mu}(v, w) \\ \Leftrightarrow CORE_{\varepsilon, \mu}(v) \wedge w \in N_{\varepsilon}(v). \end{aligned}$$

Direct structure reachability is symmetric for any pair of cores. However, it is asymmetric if one of the vertices is not a core. The following definition is a canonical extension of direct structure reachability.

Definition 6 [Structure Reachability].

Let $\varepsilon \in \mathfrak{N}$ and $\mu \in \mathfrak{S}$. A vertex $w \in V$ is structure reachable from $v \in V$ w.r.t ε and μ , if there is a chain of vertices $v_1, \dots, v_n \in V$, $v_1 = v$, $v_n = w$ such that v_{i+1} is directly structure reachable from v_i , formally:

$$\begin{aligned} REACH_{\varepsilon, \mu}(v, w) \\ \Leftrightarrow \exists v_1, \dots, v_n \in V : v_1 = v \wedge v_n = w \wedge \\ \forall i \in \{1, \dots, n-1\} : DirREACH_{\varepsilon, \mu} \\ (v_i, v_{i+1}). \end{aligned}$$

The structure reachability is transitive, but it is asymmetric. It is only symmetric for a pair of cores. More specifically, the structure reachability is a transitive closure of direct structure reachability.

Two noncore vertices in the same cluster may not be structure-reachable because the core condition may not hold for them. But they still belong to the same cluster because they both are structure reachable from the same core. This idea is formulized in the following definition of structure connectivity.

Definition 7 [Structure Connectivity].

Let $\varepsilon \in \mathfrak{N}$ and $\mu \in \mathfrak{S}$. A vertex $v \in V$ is structure-connected to a vertex $w \in V$ w.r.t ε and μ , if there is a vertex $u \in V$ such that both v and w are structure reachable from u , formally:

$$\begin{aligned} CONNECT_{\varepsilon, \mu}(v, w) \\ \Leftrightarrow \exists u \in V : REACH_{\varepsilon, \mu}(u, v) \\ \wedge REACH_{\varepsilon, \mu}(u, w). \end{aligned}$$

The structure connectivity is a symmetric relation. It is also reflective for the structure reachable vertices.

Now, we are ready to define a cluster as structure-connected vertices, which is maximal w.r.t. structure reachability.

Definition 8 [Structure-Connected Cluster]. Let $\varepsilon \in \mathfrak{N}$ and $\mu \in \mathfrak{S}$. A nonempty subset $C \subseteq V$ is called a *structure-connected cluster* (SCC) w.r.t ε and μ , if all vertices in C are structure-connected and C is maximal w.r.t structure reachability, formally:

$$SCC_{\varepsilon, \mu}(C) \Leftrightarrow$$

1. Connectivity:

$$\forall v, w \in C : CONNECT_{\varepsilon, \mu}(v, w)$$

2. Maximality:

$$\begin{aligned} \forall v, w \in V : v \in C \wedge REACH_{\varepsilon, \mu}(v, w) \\ \Rightarrow w \in C. \end{aligned}$$

Now we can define a clustering of a network G w.r.t. the given parameters ε and μ as all structure-connected clusters in G .

Definition 9 [Clustering]. Let $\varepsilon \in \mathfrak{N}$ and $\mu \in \mathfrak{S}$. A clustering P of network $G = \langle V, E \rangle$ w.r.t. ε and μ consists of all structure-connected clusters w.r.t. ε and μ in G , formally:

$$\begin{aligned} CLUSTERING_{\varepsilon, \mu}(P) \Leftrightarrow P \\ = \{C \subseteq V \mid SCC_{\varepsilon, \mu}(C)\}. \end{aligned}$$

On the basis of the clustering definition above, some vertices may not belong to any clusters. They are outliers, in the sense that structurally they are not similar to their neighbors, formally:

Definition 10 [Outlier]. Let $\varepsilon \in \mathfrak{N}$ and $\mu \in \mathfrak{S}$. For a given clustering P , that is, $CLUSTERING_{\varepsilon, \mu}(P)$, if a vertex $v \in V$ does not belong to any clusters, it is an outlier w.r.t. ε and μ , formally,

$$OUTLIER_{\varepsilon, \mu}(v) \Leftrightarrow \forall C \in P : v \notin C.$$

The outliers may play different rolls. Some outliers, such as vertex 6 in Fig. 1, connect to many clusters and act as a hub. Others, such as vertex 13 in Fig. 1, connect to relatively few clusters and are potentially outsiders because they have only weak connections to

the network. In the following, we formalize the notion of an outlier and their classification as either hubs or outsiders.

Definition 11 [Hub]. Let $\varepsilon \in \mathbb{N}$ and $\mu \in \mathbb{N}$. For a given clustering P , that is, $CLUSTERING_{\varepsilon, \mu}(P)$, if an outlier $v \in V$ has neighbors belonging to two or more different clusters w.r.t. ε and μ , it is a hub (it bridges different clusters) w.r.t. ε and μ , formally,

$$HUB_{\varepsilon, \mu}(v) \Leftrightarrow$$

1. $OUTLIER_{\varepsilon, \mu}(v)$
2. v bridges different clusters:

$$\begin{aligned} \exists p, q \in \Gamma(v) : \exists X, Y \in P : X \\ \neq Y \wedge p \in X \wedge q \in Y. \end{aligned}$$

Definition 12 [Outsider]. Let $\varepsilon \in \mathbb{N}$ and $\mu \in \mathbb{N}$. For a given clustering P , that is, $CLUSTERING_{\varepsilon, \mu}(P)$, an outlier $v \in V$ is an outsider if and only if all its neighbors belong to a single cluster or other outliers, formally,

$$OUTSIDER_{\varepsilon, \mu}(v) \Leftrightarrow$$

1. $OUTLIER_{\varepsilon, \mu}(v)$
2. v does not bridge different clusters:

$$\begin{aligned} \neg \exists p, q \in \Gamma(v) : \exists X, Y \in P : X \\ \neq Y \wedge p \in X \wedge q \in Y. \end{aligned}$$

In practice, the definition of a hub and an outsider is flexible. The more clusters an outlier bridges, the more strongly that vertex is indicated to be a hub. This point is discussed further when actual networks are considered.

The following lemmas are important for validating the correctness of our proposed algorithm. Intuitively, the lemmas mean the following. Given a network $G = \langle V, E \rangle$ and two parameters ε and μ , we can find structure-connected clusters in a two-step approach. First, choose an arbitrary vertex from V satisfying the core condition as a seed. Second, retrieve all the vertices that are structure reachable from the seed to obtain the cluster grown from the seed.

Lemma 1. Let $v \in V$. If v is a core, then the set of vertices that are structure reachable from v is a structure-connected cluster, formally:

$$\begin{aligned} CORE_{\varepsilon, \mu}(v) \wedge C &= \{w \in V | REACH_{\varepsilon, \mu}(v, w)\} \\ &\Rightarrow SCC_{\varepsilon, \mu}(C). \end{aligned}$$

Proof.

1. $C \neq \emptyset$:
By assumption, $CORE_{\varepsilon, \mu}(v)$ and thus, $REACH_{\varepsilon, \mu}(v, v) \Rightarrow v \in C$.
2. Maximality:

Let $p \in C$ and $q \in V$ and

$$\begin{aligned} REACH_{\varepsilon, \mu}(p, q) \\ \Rightarrow REACH_{\varepsilon, \mu}(v, p) \\ \wedge REACH_{\varepsilon, \mu}(p, q) \\ \Rightarrow REACH_{\varepsilon, \mu}(v, q), \\ \text{since structure reachability} \\ \text{is transitive.} \\ \Rightarrow q \in C. \end{aligned}$$

3. Connectivity:

$$\begin{aligned} \forall p, q \in C : REACH_{\varepsilon, \mu}(v, p) \\ \wedge REACH_{\varepsilon, \mu}(v, q) \\ \Rightarrow CONNECT_{\varepsilon, \mu}(p, q), \text{ via } v. \end{aligned}$$

Furthermore, a structure-connected cluster C with respect to ε, μ is uniquely determined by any of its cores, that is, each vertex in C is structure reachable from any of the cores of C and, therefore, a structure-connected cluster C contains exactly the vertices that are structure reachable from an arbitrary core of C .

Lemma 2. Let $C \subseteq V$ be a structure-connected cluster. Let $p \in C$ be a core. Then, C equals the set of vertices that are structure reachable from p , formally:

$$\begin{aligned} SCC_{\varepsilon, \mu}(C) \wedge p \in C \wedge CORE_{\varepsilon, \mu}(p) \\ \Rightarrow C = \{v \in V | REACH_{\varepsilon, \mu}(p, v)\}. \end{aligned}$$

Proof. Let $\hat{C} = \{v \in V \mid REACH_{\varepsilon, \mu}(p, v)\}$. We have to show that $C = \hat{C}$:

1. $\hat{C} \subseteq C$: it is obvious from the definition of $\hat{C}$.
2. $C \subseteq \hat{C}$: Let $q \in C$. By assumption, $p \in C \wedge SCC_{\varepsilon, \mu}(C)$.

$\Rightarrow \exists u \in C : REACH_{\varepsilon, \mu}(u, p)$
 $\quad \wedge RECH_{\varepsilon, \mu}(u, q)$
 $\Rightarrow REACH_{\varepsilon, \mu}(p, u)$,
 since both u and p are cores,
 and structure reachability
 is symmetric for cores.

$\Rightarrow REACH_{\varepsilon, \mu}(p, q)$, since structure reachability is transitive.

$\Rightarrow q \in \hat{C}$.

ALGORITHM

In this section, we describe the algorithm that implements the search for clusters, hubs, and outsiders. As mentioned in the section titled “Structure-Connected Cluster,” the search visits each vertex once to find structure-connected clusters and the outliers, and then classifies each outlier as either a hub or an outsider based on their connectivity to the clusters.

```

ALGORITHM ( $G = \langle V, E \rangle, \varepsilon, \mu$ )
// all vertices in  $V$  are labeled as unclassified;

for each unclassified vertex  $v \in V$  do
// STEP 1. check whether  $v$  is a core;
  if  $CORE_{\varepsilon, \mu}(v)$  then
// STEP 2.1. if  $v$  is a core, a new cluster is expanded;
    generate new cluster ID;
    insert all  $x \in N_{\varepsilon}(v)$  into queue  $Q$ ;
    while  $Q \neq \emptyset$  do
       $y$  = first vertex in  $Q$ ;
       $R = \{x \in V \mid \text{DirRECH}_{\varepsilon, \mu}(y, x)\}$ ;
      for each  $x \in R$  do
        if  $x$  is unclassified or an outlier then
          assign current cluster ID to  $x$ ;
        if  $x$  is unclassified then
          insert  $x$  into queue  $Q$ ;
      remove  $y$  from  $Q$ ;
    else
// STEP 2.2. if  $v$  is not a core, it is labeled as an outlier
      label  $v$  as outlier;
    end for.
// STEP 3. further classifies outliers
for each outlier  $v$  do
  if  $(\exists x, y \in \Gamma(v) \mid x.\text{clusterID} \neq y.\text{clusterID})$  then
    label  $v$  as hub
  else
    label  $v$  as outsider;
  end for.
end.

```

Figure 2. The pseudocode of our algorithm.

The pseudocode of the algorithm is presented in Fig. 2. The algorithm performs one pass of a network and finds all structure-connected clusters for a given parameter setting. At the beginning, all vertices are labeled as unclassified. The algorithm either assigns a vertex to a cluster or labels it as an outlier. For each vertex that is not yet classified, it checks whether this vertex is a core (STEP 1 in Fig. 2). If the vertex is a core, a new cluster is expanded from this vertex (STEP 2.1 in Fig. 2). Otherwise, the vertex is labeled as an outlier (STEP 2.2 in Fig. 2). To find a new cluster, the algorithm starts with an arbitrary core v and search for all vertices that are structure-reachable from v in STEP 2.1. This is sufficient to find the complete cluster containing vertex v , due to Lemma 2. In STEP 2.1, a new cluster ID is generated that will be assigned to all vertices found in STEP 2.1. The algorithm begins by inserting all vertices in ε -neighborhood of vertex v into a queue. For each vertex in the queue, it computes all directly reachable vertices and inserts those vertices into the queue that are still unclassified. This is repeated until the queue is empty.

The outliers can be further classified as hubs or outsiders in STEP 3. If an outlier connects to two or more clusters, it is classified as a hub. Otherwise, it is an outsider. This final classification is done according to what is appropriate for the network. As mentioned earlier, the more the clusters in which an outlier has neighbors, the more strongly that vertex acts as a hub between those clusters. Likewise, a vertex might bridge only two clusters, but how strongly it is viewed as a hub may depend on how aggressively it bridges them.

As discussed in the section titled “The Notion of Structure-Connected Cluster,” the results of our algorithm do not depend on the order the vertices are processed. The partitioning (number of clusters and association of cores to clusters) is determinate.

COMPLEXITY ANALYSIS

In this section, we present an analysis of the computation complexity of the algorithm.

Given a network with m edges and n vertices, we first find all structure-connected clusters w.r.t. a given parameter setting by checking each vertex of the network (STEP 1 in Fig. 2). This entails retrieval of all the vertex’s neighbors. Using an adjacency list, a data structure where each vertex has a list of which vertices it is adjacent to, the cost of a neighborhood query is proportional to the number of neighbors, that is, the degree of the query vertex. Therefore, the total cost is $O(\deg(v_1) + \deg(v_2) + \dots + \deg(v_n))$, where $\deg(v_i)$, $i = 1, 2, \dots, n$ is the degree of vertex v_i . If we sum all the vertex degrees in G , we count each edge exactly twice: once from each end. Thus the running time is $O(m)$.

We also derive the running time in terms of the number of vertices, should the number of edges be unknown. In the worst case, each vertex connects to all the other vertices for a complete graph. The worst case total cost, in terms of the number of vertices, is $O(n(n-1))$, or $O(n^2)$. However, real networks generally have sparser degree distributions. In the following, we derive the complexity for an average case, for which we know the probability distribution of the degrees. One type of network is the random graph, studied by Erdős and Rényi [11]. Random graphs are generated by placing edges randomly between vertices. Random graphs have been employed extensively as models of real-world networks of various types, particularly in epidemiology. The degree of a random graph has a Poisson distribution:

$$p(k) = \binom{n}{k} p^k (1-p)^{n-k} \approx \frac{z^k e^{-z}}{k!},$$

which indicates that most nodes have approximately the same number of links (close to the average degree $E(k) = z$). In the case of random graphs the complexity of the algorithm is $O(n)$.

Many real networks, such as social networks, biological networks, and the WWW follow a power-law degree distribution. The probability that a node has k edges, $P(k)$, is on the order $k^{-\alpha}$, where α is the degree exponent. A value between 2 and 3 was observed for the degree exponent for most biological and non-biological networks studied by the Faloutsos

et al. [12] and Barabási and Oltvai [13]. The expected value of degree is $E(k) = \alpha/(\alpha - 1)$. In this case, the average cost of the algorithm is again $O(n)$.

We conclude that the complexity in terms of the number of edges in the network for our algorithm is, in general, linear. The complexity in terms of the number of vertices is quadratic in the worst case of a complete graph. For real networks like social networks, biological networks, and computer networks, we expect linear complexity with respect to the number of vertices. This is confirmed by our empirical study described in the next section.

EVALUATION

In this section we evaluate our algorithm using both synthetic and real datasets. We first compared the different structural similarities defined in the section titled “Structure-Connected Cluster” for the accuracy of the clustering. The performance of the algorithm is then compared with fast modularity-based network clustering algorithm proposed in Clauset *et al.* [5], which is faster than many competing algorithms: its running time on a network with n vertices and m edges is $O(md \log n)$ where d is the depth of the dendrogram describing the hierarchical cluster structure. We implemented our algorithm in C++. We used the original source code of fast modularity algorithm by Clauset *et al.* [14]. All the experiments were conducted on a PC with a 2.0 GHz Pentium 4 processor and 1 GB of RAM.

Efficiency

To evaluate the computational efficiency of the proposed algorithm, we generated 10 networks with the number of vertices ranging from 1000 to 1,000,000 and the number of edges ranging from 2182 to 2,000,190. We adapted the construction as used in Newman and Girvan [3] as follows: first we generate clusters such that each vertex connects to vertices within the same cluster with a probability P_i , and connects to vertices outside its cluster with a probability $P_o < P_i$. Next, we add a number of hubs and outsiders. An

example of a generated network is presented in Fig. 3.

The running time for fast modularity and our algorithm on the synthetic networks are plotted in Figs 4 and 5, respectively. The running time is plotted both as a function of the number of nodes and the number of edges. Figure 5 shows that our algorithm’s running time is in fact linear w.r.t. to the number of vertices and the number of edges, while fast modularity’s running time is basically quadratic and scales poorly for large networks. Note the difference in scale for the y-axis between the two figures.

Effectiveness

To evaluate the effectiveness of network clustering, we use real datasets whose clusters are known *a priori*. These real datasets include American College Football and Books about US politics. We also apply the clustering algorithm to customer data integration. We use adjusted Rand index (ARI) [15] as a measure of effectiveness of network clustering algorithms in addition to visually comparing the generated clusters to the actual.

Adjusted Rand Index. A measure of agreement is needed when comparing the results of a network clustering algorithm to the expected clustering. Rand index [16] serves this purpose. One problem with the Rand index is that the expected value is not constant when comparing two random clusters. An ARI was proposed by Hubert and Arabie [15] to fix this problem. The ARI is defined as follows:

$$\frac{\sum_{i,j} \binom{n_{ij}}{2} - \left[\sum_i \binom{n_i}{2} \sum_j \binom{n_j}{2} \right] / \binom{n}{2}}{\frac{1}{2} \left[\sum_i \binom{n_i}{2} + \sum_j \binom{n_j}{2} \right] - \left[\sum_i \binom{n_{i,i}}{2} \sum_i \binom{n_{j,j}}{2} \right] / \binom{n}{2}},$$

where $n_{i,j}$ is the number of vertices in both clusters x_i and y_j ; and $n_{i,\cdot}$ and $n_{\cdot,j}$ are the number of vertices in cluster x_i and y_j , respectively.

Figure 3. A Synthetic network with 1000 vertices.

Figure 4. Running time for fast modularity algorithm.

Figure 5. Running time for our algorithm.

Milligan and Cooper [17] evaluated many different indices for measuring agreement between two network clustering with different numbers of clusters and recommended the ARI as the measure of choice. We adopt the ARI as our measure of agreement between the network clustering result and the true clustering of the network. The ARI lies between 0 and 1. When the two clustering agree perfectly, the ARI is 1.

Performance of Various Structural Similarities. Our algorithm groups vertices based on their structural similarity. We compared the various structural similarities defined in the section titled “Structure-Connected Cluster” for the accuracy of the clusters they generate, measured by ARI. The results on real networks including college football, political books, and customers described in the sections titled “College Football,” “Books About US Politics,” and “Customer Data Integration,” respectively are listed in Table 1.

The cosine similarity (σ_{cos}) achieves overall the best accuracy in comparison with other similarity measures. In our following experiments, we use cosine similarity for our algorithm.

College Football. The first real dataset we examine is the 2006 National Collegiate Athletic Association (NCAA) Football Bowl Subdivision (formerly Division 1-A) football schedule. This example is inspired by the set studied by Newman and Girvan [3], who consider contests between Division 1-A teams in 2000. Our set is more complex; we consider all contests of the Bowl Subdivision schools including those against schools in lower divisions.

Table 1. Performance of Various Structural Similarities

	COSINE (σ_{cos})	MIN (σ_{min})	JACCARD (σ_{jaccard})
College football	1	0.255	0.983
Political books	0.708	0.661	0.574
CG1	1	1	1
CG2	1	0.942	1

The challenge is to discover the underlying structure of this network—the college conference system. The NCAA divides 115 schools into 11 conferences. In addition, there are four independent schools at this top level: Army, Navy, Temple, and Notre Dame. Each Bowl Subdivision school plays against schools within their own conference, against schools in other conferences, and against lower division schools. The network contains 180 vertices (119 Bowl Subdivision schools and 61 lower division schools) interconnected by 787 edges. Figure 6 shows this network with schools in the same conference identified by color.

This example illustrates the kinds of structures that our method seeks to address. Schools in the same conference are clusters. The four independent schools play teams in many conferences but belong to none; they are called *hubs*. The lower division schools are only connected weakly to the clusters in the network; they are called *outsiders*.

First we cluster this network by using the fast modularity algorithm. The results, for which the modularity is 0.599 is shown in Fig. 7. Maximizing Newman’s modularity gives a satisfying network clustering, identifying nine clusters. All schools in the same conference are clustered together. However, two of the conferences are merged (the Western Athletic and Mountain West conferences and the Mid-American and Big Ten conferences), the four independent schools are classified into various conferences despite their hub-like properties. All lower division teams are assigned to clusters.

Next, we cluster the network using our algorithm, using the parameters ($\varepsilon = 0.5$, $\mu = 2$). This clustering succeeds in capturing all the features of the network. The 11 clusters are identified, corresponding exactly to the 11 conferences. All schools in the same conference are clustered together. The independent schools and the lower division schools are unclassified; they stand apart from the clusters. The four independent schools show strong properties as hubs; they have inactive edges that connect them to a large number of clusters—at minimum five. In contrast, the lower division schools have only weak connections to clusters, one or

Figure 7. NCAA Football Bowl Subdivision schedule as clustered by fast modularity algorithm.

Figure 8. Political book network.

two, and in a single case three. They are true outsiders. This clustering matches perfectly with the underlying structure shown in Fig. 6.

Books about US Politics. The second example is the classification of books about US politics. We use the dataset of books about US politics compiled by Valdis Krebs [18]. The vertices represent books about US politics sold by the online bookseller Amazon.com. The edges represent frequent copurchasing of books by the same buyers, as indicated by the “customers who bought this book also bought these other books” feature on Amazon. The vertices have been given values “l,” “n,” or “c” to indicate whether they are “liberal,” “neutral,” or “conservative.” These alignments were assigned separately by Mark Newman [19] based on a reading of the descriptions and reviews of the books posted on Amazon. The political books network is illustrated in Fig. 8. The “conservative,” “neutral,” and “liberal” books are represented by red, gray, and blue, respectively.

First, we apply our algorithm to the political books network, using the parameters ($\varepsilon = 0.35$, $\mu = 2$). Our goal is to find clusters that represent the different political orientations of the books. The result is presented in Fig. 9. Our algorithm successfully finds

three clusters representing “conservative,” “neutral,” and “liberal” books, respectively. The obtained clusters are illustrated using three different shapes: squares for “conservative” books, triangles for “neutral” books, and circles for “liberal” books. In addition, each vertex is labeled with the book title.

The result for the fast modularity algorithm is presented in Fig. 10. The fast modularity algorithm found four clusters, presented using circles, triangles, squares, and hexagons. Although two dominant clusters, represented by circles and squares, align well with the “conservative” and “liberal” classes, the “neutral” class is mostly misclassified. This demonstrates again that fast modularity algorithm cannot handle vertices that bridge clusters.

Customer Data Integration. Finally we apply the network clustering algorithms to detect groups of records for the same individual, a problem called customer data integration (CDI). A large database of records consisting of names and addresses are matched against each other. The database contains multiple records for the same individual, but they manifest variations in the names and addresses whose causes range from the use of nicknames and abbreviations to data entry errors. If two records match, we

Figure 9. The result of our algorithm on political book network.

Figure 10. The result of fast modularity algorithm on political book network.

connect them with an edge. From a large file we extract sets of interconnected records for study. We test two networks, CG1 and CG2 (shown in Fig. 11). Network CG1 represents data for two individuals and two poor-quality records that represent no true individual. Network CG2 represents four individuals, one of whom is represented by a single instance.

The clustering results of our algorithm, using the parameters ($\varepsilon = 0.7, \mu = 2$), are presented in Fig. 12. The results demonstrate that it successfully found all the clusters and outliers. The results of fast modularity

algorithm are presented in Fig. 13. It is clear that it failed to identify any outliers.

Adjusted Rand Index Comparison. As mentioned in the section titled “Adjusted Rand Index,” the ARI is an effective measure of the similarity of a clustering result to the true clustering. The results for College Football, Political Books, CG1 and CG2 are presented in Table 2.

The ARI results clearly demonstrate that the proposed algorithm outperforms the fast modularity algorithm and produces clustering that resemble the true clustering for the real-world networks in our study.

Table 2. Adjust Rand Index Comparison

	Our Algorithm	Fast Modularity Algorithm
College football	1	0.24
Political books	0.71	0.64
CG1	1	0.85
CG2	1	0.68

Input Parameters. Our algorithm uses two parameters: ε and μ . To choose them we

adapted the heuristic suggested for DBSCAN in Ester *et al.* [9]. This involves making a k -nearest neighbor query for a sample of vertices and noting the nearest structural similarity as defined in the section titled “Structure-Connected Cluster.” The query vertices are then sorted in ascending order of nearest structural similarity. A typical k -nearest similarity plot is shown in Fig. 14. The knee indicated by a vertical line shows that an appropriate ε value for this network is 0.7. This knee represents a separation of

Figure 14. Sorted k -nearest structural similarity.

vertices belonging to clusters to the right from hubs and outliers to the left. Usually a sample of 10% of the vertices is sufficient to locate the knee. In the absence of such an analysis, an ε value between 0.5 and 0.8 is normally sufficient to achieve a good clustering result. We recommend a value of 2 for μ .

RELATED WORK

Network clustering is the division of a network into set of subnetworks, called *clusters*. More specifically, given a network $G = \{V, E\}$, where V is a set of vertices and E is a set of edges between vertices, the goal of network clustering is to divide G into k disjoint subnetworks $G_i = \{V_i, E_i\}$, in which $V_i \cap V_j = \emptyset$ for any $i \neq j$, and $V = \sum_{i=1}^k V_i$. The number of subnetworks, k , may or may not be known a priori. In this article, we focus on simple, undirected, and unweighted networks.

The problem of finding good clusters for networks has been studied for some decades in many fields, particularly computer science and physics. Here we review some of the more common methods.

The *min-max cut method* [1] seeks to cluster a network $G = \{V, E\}$ into two clusters A and B . The principle of min-max clustering is minimizing the number of connections between A and B and maximizing the number of connections within each. A *cut* is defined by the number of edges that would have to be removed to isolate the vertices in cluster A from those in cluster B . The min-max

cut algorithm searches for the clustering that creates two clusters whose *cut* is minimized while maximizing the number of remaining edges.

A pitfall of this method is that, if one cuts out a single vertex from the network, one will probably achieve the optimum. Therefore, in practice, the optimization must be accompanied with some constraint, such as A and B should be of equal or similar size, or $|A| \approx |B|$. Such constraints are not always appropriate; for example, in social networks some communities are much larger than the others.

To amend the issue, a *normalized cut* was proposed [2], which normalizes the cut by the total number of connections between each cluster to the rest of the network. Therefore, cutting out one vertex or some small part of the network will no longer always yield an optimum.

Both min-max cut and normalized cut methods cluster a network into two clusters. To divide a network into k clusters, one has to adopt a top-down approach, splitting the network into two clusters, and then further splitting these clusters, and so on, until k clusters have been detected. There is no guarantee of the optimality of recursive clustering. There is no measure of the number of clusters that should be produced when k is unknown. There is no indicator to stop the bisection procedure.

Recently, *modularity* was proposed as a quality measure of network clustering [3]. For a clustering of network with k clusters,

the modularity is defined as follows:

$$Q = \sum_{s=1}^k \left[\frac{l_s}{L} - \left(\frac{d_s}{2L} \right)^2 \right],$$

L is the number of edges in the network, l_s is the number of edges between vertices within cluster s , and d_s is the sum of the degrees of the vertices in cluster s . The modularity of a clustering of a network is the fraction of all edges that lie within each cluster minus the fraction that would lie within each cluster if the network's vertices were randomly connected. Optimal clustering is achieved when the modularity is maximized. Modularity is defined such that it is 0 for two extreme cases: when all vertices clustered into a single cluster, and when the vertices are clustered at random. Note that the modularity measures the quality of any network clustering. Normalized and min-max cut measures only the quality of a clustering of two clusters.

Finding the maximum Q is NP-complete. Instead of performing an exhaustive search, various optimization approaches are proposed. For example, a greedy method based on a hierarchical agglomeration clustering algorithm is proposed in Clauset *et al.* [5], which is faster than many competing algorithms: its running time on a network with n vertices and m edges is $O(md \log n)$ where d is the depth of the dendrogram describing the hierarchical cluster structure. Also, Guimera and Amaral [4] optimize modularity using simulated annealing.

To summarize, the network clustering methods discussed in this section aim to find clusters such that there are many connections between vertices within the same clusters and few without. While all these network clustering methods successfully find clusters, they are generally unable to detect hubs and outsiders like those in the example in Fig. 1. Such vertices invariably are included in one cluster or another.

CONCLUSIONS

Organizing related data is a fundamental task in many fields of science and

engineering. Many algorithms for partitioning networks have been proposed by practitioners in different disciplines including computer science and physics. Successful examples are min-max cut [1] and normalized cut [2], as well as modularity-based network clustering algorithms [3–5]. While such algorithms can successfully detect clusters in networks, they tend to fail to identify and isolate two kinds of vertices that play special roles: vertices that bridge clusters (hubs) and vertices that are marginally connected to clusters (outsiders). Identifying hubs is particularly valuable for applications such as viral marketing and epidemiology. As vertices that bridge clusters, hubs are responsible for spreading ideas or disease. In contrast, outsiders have little or no influence, and may be isolated as noise in the data.

In this article, we proposed a new algorithm to detect clusters, hubs, and outsiders in networks. It clusters vertices based on their common neighbors. Two vertices are assigned to a cluster according to how they share neighbors. This makes sense when you consider social communities. People who share many friends create a community, and the more friends they have in common, the more intimate the community. But in social networks there are different kinds of actors. There are also people who are outsiders (like hermits), and there are people who are friendly with many communities but belong to none (like politicians). The latter play a special role in small-world networks [10].

We applied our algorithm to some real-world networks including finding conferences using only the NCCA College Football schedule, grouping political books based on copurchasing information, and customer data integration. In addition, we compared the new algorithm with the fast modularity-based algorithm in terms of both efficiency and effectiveness. The theoretical analysis and empirical evaluation demonstrate superior performance over the modularity-based network clustering algorithm.

In the future we plan to apply our algorithm to analyze biological networks such as metabolic networks and gene coexpression networks.

ACCELERATED LIFE MODELS

MIKHAIL NIKULIN
IMB, Université Victor Segalen,
Bordeaux, France

INTRODUCTION

We consider dynamic regression models which are well adapted to study the phenomena of longevity, aging, fatigue, and degradation of complex systems, and hence appropriate to be used in the organization of the efficient statistical process of quality control in dynamic environments.

It is well known that traditionally only the failure time data are usually used for the product reliability estimation or the estimation of survival characteristics. Failures of highly reliable units are rare, for example, the lifetime of semiconductors is very long, and to test devices under usual conditions would require too much test time and excessively large sample size. So other information should be used in addition to failure time data, which could be censored.

One way of obtaining a complementary reliability information is to use higher level of experimental factors, stresses or covariates (such as temperature, voltage or pressure) to increase the number of failures and hence to obtain reliability information quickly. This procedure provides the methods known today as the accelerated life testing (ALT). This method is described very well in statistical literature [1–6].

The ALT of technical or biotechnical systems is an important practical statistical method of estimation of the reliability and the quality improvement of new systems without waiting for the operating life of an item. The ALT has been recognized as a necessary activity to ensure the reliability of electronic products used in military, aerospace, automotive and mobile (cellular, laptop computers) applications, from which one can see

that accelerated testing of electronic products offers great potential for improving the reliability life testing, to obtain expected reliability results for the products more quickly than under normal operating conditions, given in terms of covariates (stresses), which could be time-varying. It is interesting to study the possibility of taking into account the cumulative effect of the applied stresses on aging, fatigue, and degradation of testing items or systems. It is evident that the extrapolating reliability or quality from the ALT always carries the risk that the accelerated stresses do not properly excite the failure mechanism, which dominates at operating (normal) stresses.

Another way of obtaining complementary reliability information is to measure some parameters, which characterize the aging or wear of the product in time. In analysis of longevity of highly reliable complex industrial or biological systems, the degradation processes provide an important additional information about the aging, degradation, and deterioration of systems, and from this point of view these degradation data are really a very rich source of reliability information and often offer many advantages over failure time data. Degradation is the natural response for some tests, and it is also natural that with degradation data it is possible to make useful reliability and statistical inference even with no observed failure. It is evident that sometimes it may be difficult and costly to collect degradation measures from some components or materials. Sometimes it is possible to apply the expert's estimation of the level of degradation.

Statistical inference from ALT is possible, if failure time regression models relating failure time distribution with external explanatory variables (covariates, stresses) influencing the reliability are well chosen. Statistical inference from failure time-degradation data with covariates needs even more complicated models relating failure time distribution not only with external but also with internal explanatory variables

(degradation, wear), which explain the state of units before the failures. In the last case, models for degradation process distribution are needed too.

In this paper we discuss the most-used failure time regression models used for analysis of failure time and failure time-degradation data with covariates.

NOTATIONS

Let us denote by T the random time-to-failure of a unit (or system). We also say that T is the time of *hard* or *traumatic failure*. Let S be the survival function and λ be the hazard rate, then

$$\begin{aligned} S(t) &= \mathbf{P}\{T > t\}, \\ \lambda(t) &= \lim_{h \rightarrow 0} \frac{1}{h} \mathbf{P}\{t \leq T < t+h | T \geq t\} \\ &= -\frac{d[\ln S(t)]}{dt} \end{aligned} \quad (1)$$

from where it follows that $S(\cdot)$ can be written as

$$S(t) = e^{-\Lambda(t)}, \quad \text{where} \quad \Lambda(t) = \int_0^t \lambda(s) ds$$

is the cumulative hazard function. $F(\cdot) = 1 - S(\cdot)$ is the cumulative distribution function of T . In survival analysis and reliability, the models are often formulated in terms of hazard rate functions. The most common shapes of hazard rates are monotone, $\cup$ -shaped or $\cap$ -shaped; for example, Ref. 7.

If the form of the survival or other equivalent function is supposed to be known and this function depends only on finite-dimensional parameter, the corresponding model is parametric. Classes of parametric models used in reliability are given in Refs 3, 5 and 6.

Suppose the explanatory variable is a deterministic time function

$$x = x(\cdot) = (x_1(\cdot), \dots, x_m(\cdot))^T : [0, \infty[\rightarrow B \in \mathbb{R}^m,$$

which is a vector of covariates itself or a realization of a stochastic process $X(\cdot)$, which is also called the covariate process, $X(\cdot) = (X_1(\cdot), \dots, X_m(\cdot))^T$. We denote by E , the set of

all possible (admissible) covariates and by E_1 , the set of all constants over time covariates, $E_1 \subset E$. We do not discuss here the questions of choice of X_i and m , but they are very important for the planning (design) of the experiments and for statistical inference. The covariates can be interpreted as the control [8], since we may consider models of aging in terms of differential equations and therefore use all theory and techniques from the optimal control theory. We may say that we consider statistical modeling with dynamic design or in dynamic environments.

Let $E_2, E_2 \subset E$, be a set of step-stresses of the form

$$x(t) = x_1 1_{\{0 \leq t < t_1\}} + x_2 1_{\{t_1 \leq t\}}, \quad x_1, x_2 \in E_1. \quad (2)$$

In accordance with Equation (1), the survival, the hazard rate, the cumulative hazard, and the distribution functions given x are

$$\begin{aligned} S(t|x) &= \mathbf{P}(T > t|x(s); 0 \leq s \leq t), \\ \lambda(t|x) &= -\frac{S'(t|x)}{S(t|x)}, \\ \Lambda(t|x) &= -\ln[S(t|x)], \\ F(t|x) &= \mathbf{P}(T \leq t|x(s); 0 \leq s \leq t) = 1 - S(t|x), \\ &x \in E, \end{aligned}$$

from where one can see their dependence on the life-history up to time t . On any family E of admissible stresses, we may consider a class $\{S(\cdot|x), x \in E\}$ of survival functions which could be very rich.

We say that the time $f(t|x)$ under the stress x_0 is *equivalent* to the time t under the stress x if the probability that a unit used under the stress x would survive till the moment t is *equal* to the probability that a unit used under the stress x_0 would survive till the moment $f(t|x)$:

$$\begin{aligned} S(t|x) &= \mathbf{P}\{T > t|x(s); 0 \leq s \leq t\} \\ &= \mathbf{P}\{T > f(t|x)|x_0(s); 0 \leq s \leq f(t|x)\} \\ &= S(f(t|x)|x_0). \end{aligned}$$

It implies that:

$$f(t|x) = S^{-1}[S(t|x)|x_0], \quad x \in E. \quad (3)$$

Let x and y be two admissible stresses: $x, y \in E$. We say that a stress y is *accelerated* with respect to x , if:

$$\begin{aligned} S(t|x) &\geq S(t|y), \quad \forall t \geq 0, \\ S(\cdot|x), S(\cdot|y) &\in \{S(\cdot|z), z \in E\}. \end{aligned}$$

ACCELERATED LIFE AND FAILURE TIME REGRESSION MODELS

Failure time regression models relating the lifetime distribution to possibly time dependent external explanatory variables are considered in this section. Failure time regression models relates failure time distribution not only with external but also with internal explanatory variables will be discussed in the next section. Now, such models are used not only in reliability but also in demography, dynamics of populations, gerontology, biology, survival analysis, genetics, radiobiology, biophysics; everywhere people study the problems of longevity, aging, and degradation using stochastic modeling.

In reliability, ALT in particular, the choice of a good regression model often is more important than in survival analysis. For example, in ALT units are tested under accelerated stresses which shorten the life. Using such experiments the life under the usual stress is estimated using some regression model. The values of the usual stress are often not in the range of the values of accelerated stresses, since the wide separation between experimental and usual stresses is possible; so if the model is mis-specified, the estimators of survival under the usual stress may be very bad.

Sedyakin's Model

The physical principle in reliability, proposed by Sedyakin [9], gives an interesting way to prolong any class of survival functions $\{S(\cdot|x), x \in E_1\}$ indexed by constant in time stresses to a class of survival functions indexed by step-stresses, for example, from E_2 , given by Equation (2).

According to Sedyakin we may consider the next model on E_2 : if two moments t_1 and

t_1^* are equivalent, that is, the probabilities of survival until these moments under stresses x_1 and x_2 , respectively, are equal, that is, $S(t_1|x_1) = S(t_1^*|x_2)$, then

$$\lambda(t_1 + s|x) = \lambda(t_1^* + s|x_2), \quad \forall s \geq 0, \quad (4)$$

with x defined by Equation (2). The meaning of this rule of time-shift for these step-stresses on E_2 one can also see in terms of the survival functions:

$$S(t|x) = \begin{cases} S(t|x_1), & 0 \leq t < t_1, \\ S(t - t_1 + t_1^*|x_2), & t \geq t_1. \end{cases} \quad (5)$$

The model given by Equation (4) (or Eq. 5) is called the *Sedyakin's model* on E_2 .

The general Sedyakin (GS) model Bagdonavičius and Nikulin (2000) generalizes this idea, by supposing that the hazard rate at any moment t depends on the stress at this moment and on the probability of survival until this moment:

$$\lambda(t|x) = g(x(t), S(t|x)), \quad x \in E.$$

The Sedyakin's model is too wide for ALT and failure time regression data analysis. It only states that units which did not fail until equivalent moments under different stresses have the same risk to fail after these moments under identical stresses. Nevertheless, this model is useful for construction of narrower models and for analysis of redundant systems. At the end of this section, we note that recently [10] studied an interesting application of Sedyakin's and the accelerated failure time (AFT) model for analysis of reliability of redundant systems with one main unit and $m - 1$ stand-by units operating in "warm" conditions, that is, under lower stress than the main one.

Accelerated Failure Time Model

AFT model is more adapted for failure time regression analysis [2,3,5,6,25,26]. In ALT, it is the most-used model.

We say that AFT model holds on E if there exists a positive continuous function $r : E \rightarrow \mathbf{R}^1$ such that for any $x \in E$, the survival and the cumulative hazard functions under a covariate realization x are given by formulas:

$$S(t|x) = G\left(\int_0^t r[x(s)] ds\right) \quad \text{and} \\ \Lambda(t|x) = \Lambda_0\left(\int_0^t r[x(s)] ds\right), \quad x \in E \quad (6)$$

respectively, where $G(t) = S(t|x_0)$, $\Lambda_0(t) = -\ln G(t)$, x_0 is a given (usual) stress, $x_0 \in E$. The function r changes locally with the timescale. From the definition of $f(t|x)$ (Eq. 3) it follows that for the AFT model on E

$$f(t|x) = \int_0^t r[x(s)] ds, \quad \text{hence} \\ \frac{\partial f(t|x)}{\partial t} = r(x(t)) \quad \text{at the continuity points} \\ \text{of } r[x(\cdot)]. \quad (7)$$

Note that the model can be considered as parametric (r and G belong to parametric families) semiparametric (one of these functions is unknown, other belongs to a parametric family) or nonparametric (both are unknown). The AFT model can also be given by the next formula:

$$\lambda(t|x) = r(x(t)) \quad q(\Lambda(t|x)), \quad x \in E. \quad (8)$$

This equality shows that different from the famous Cox model, the hazard rate $\lambda(t|x)$ is proportional not only to some functions of the stress at the moment t but also to a function of the cumulative hazard $\Lambda(t|x)$ at the moment t . It means that the hazard rate at the moment t depends not only on the stress applied at this moment but also on the stress applied in the past, that is, in the interval $[0, t]$.

In parametric modeling, a baseline survival function G is taken from some class of parametric distributions such as Weibull, log-normal, log-logistic etc., and the function r is taken in the form $r(x) = e^{\beta^T \varphi(x)}$, where $\varphi(x)$ is a specified, possibly multidimensional function of x [3,6]. A versatile model is obtained when G belongs to the *power generalized Weibull* (PGW) family of distributions [4]. In terms of the survival functions, the PGW family is given by the next formula

$$S(t, \sigma, \nu, \gamma) = \exp \left\{ 1 - \left[1 + \left(\frac{t}{\sigma} \right)^\nu \right]^{\frac{1}{\gamma}} \right\}, \\ t > 0, \gamma > 0, \nu > 0, \sigma > 0. \quad (9)$$

If $\gamma = 1$, we have the Weibull family of distributions. If $\gamma = 1$ and $\nu = 1$, we have the exponential family of distributions. This class of distributions has nice probability properties. For various values of the parameters, the hazard rate can be *constant*, *monotone* (increasing or decreasing), *unimodal* or $\cap$ -shaped, and *bathtub* or $\cup$ -shaped.

Semiparametric estimation procedures for the AFT model are given in Ref. 11 and developed by many authors. Nonparametric estimation procedures with special plans of experiments are given in Ref. 12. The AFT model is popular in reliability theory because of its *interpretability*, its convenient mathematical properties and its consistency with some engineering and physical principles. Nevertheless, the assumption that the survival distributions under different covariate values differ only in scale is rather *restrictive*.

Changing Shape and Scale (CHSS) Model

A natural generalization of the AFT model [3,6], the changing shape and scale (CHSS) model is obtained by supposing that different constant stresses $x \in E_1$ influence not only the scale but also the shape of the survival distribution: there exist positive functions on E_1 $\theta(x)$ and $\nu(x)$ such that for any $x \in E_1$

$$S(t|x) = S \left\{ \left(\frac{t}{\theta(x)} \right)^{\nu(x)} \middle| x_0 \right\}; \quad (10)$$

here x_0 is fixed stress, for example, design (usual) stress. Let us consider generalizations of the model (Eq. 10) to the case of time-varying stresses. We say that the CHSS model [13], holds on E if there exist two positive functions r and ν on E such that for all $x(\cdot) \in E$:

$$S(t|x) = S \left(\int_0^t r\{x(\tau)\} \tau^{\nu(x(\tau))-1} d\tau \middle| x_0 \right), \quad x \in E.$$

The variation of stress locally changes not only the scale but also the shape of distribution. In terms of the hazard rate, the CHSS

model can be written in the form:

$$\lambda(t|x) = r\{x(t)\}q(\Lambda(t|x))t^{v(x(t))-1}. \quad (11)$$

This model is not in the class of the GS models because the hazard rate $\lambda(t|x)$ depends not only on $x(t)$ and $\Lambda(t|x)$ but also on t . Generally it is recommended to choose $v(x) = e^{\gamma T x}$. Statistical analysis of the CHSS model is done in Ref. 14, and an interesting application is considered in Ref. 8.

FAILURE TIME-DEGRADATION MODELS WITH EXPLANATORY VARIABLES

Failures of highly reliable units are rare. As we saw, one way of obtaining complementary information is to use higher levels of experimental factors or covariates, that is, ALT. In previous sections, we described the most-applied ALT models. Other ways of obtaining this complementary information is to measure some parameters characterizing degradation or damage of the unit (the product) in time. Both methods can be combined. Here, we consider some approaches to model the relationship between failure time data and degradation data with external covariates.

Statistical modeling of observed degradation processes can help to understand the different real physical, chemical, medical, biological, physiological, or social degradation processes of aging, due to cumulated wear and tiredness. The information about real degradation processes helps us to construct degradation models, which permit us to predict the cumulative damage. Suppose that the following data may be available for reliability characteristics estimation: failure times (possibly censored), explanatory variables (covariates, stresses) and the values of some observable quantity characterizing the degradation of units. We call a failure nontraumatic when the degradation attains a critical level z_0 . Other failures are called traumatic.

The failure rate of traumatic failure may depend on covariates, degradation level and time.

Good reviews on failure time-degradation data modeling are given in Refs 13, 15–17.

We develop the models given in these excellent papers. Suppose that under fixed constant covariate the degradation is non-decreasing stochastic process $Z(t), t \geq 0$ with right continuous trajectories with finite left hand limits. Denoted by $T^{(tr)}$, the moment of the traumatic failure and by $\lambda^{(tr)}(t|Z) = \lambda^{(tr)}(t|Z(s), 0 \leq s \leq t)$ the conditional hazard rate of the traumatic failures given the degradation Z till time t .

Suppose that this conditional hazard rate has *two additive components*: one, λ , related to observed degradation values, other, μ , related to nonobservable degradation (aging) and to possible shocks causing sudden traumatic failures. For example, observable degradation of tires is the wear of the protector. The failure rate of tire explosion depends on thickness of the protector, on nonmeasured degradation level of other tire components and on intensity of possible shocks (hitting a kerb, nail). So the hazard rate of the traumatic failure is modeled as follows:

$$\lambda^{(tr)}(t|Z) = \lambda(Z(t)) + \mu(t).$$

The function $\lambda(z)$ characterizes the dependence of the rate of traumatic failures on degradation. Suppose that covariates influence degradation rate and traumatic event intensity. In such case the model needs to be modified.

Let $x = (x_1, \dots, x_m)^T$ be a vector of s possibly time dependent one-dimensional covariates. We assume in what follows that x_i are deterministic or realizations of bounded right continuous with finite left hand limits stochastic processes. Denote informally by $Z(t|x)$ the degradation level at the moment t for units functioning under the covariate x . We suppose that the covariates influence locally the scales of the traumatic failure time distribution component related to nonobservable degradation (aging) and to possible shocks, that is, the AFT model is true for this component.

Let us explain it in detail. Let us denote

$$S_1^{(tr)}(t|Z) = \exp \left\{ - \int_0^t \lambda[Z(u)] du \right\},$$

$$S_2^{(tr)}(t) = \exp \left\{ - \int_0^t \mu(u) du \right\}$$

as the survival functions correspond to the hazard rates $\lambda(Z(u))$ and $\mu(u)$. The first survival function is conditional given the degradation.

The AFT model defines the following relation of the second survival function and the covariates

$$S_2^{(tr)}(t|x) = S_2 \left(\int_0^t e^{\gamma T x(s)} ds \right);$$

the parameters γ have the same dimension as x . Set

$$f(t, x, \beta) = \int_0^t e^{\beta T x(u)} du,$$

and denote by $g(t, x, \beta)$ the inverse of $f(t, x, \beta)$ with respect to the first argument. The function $f(t, x, \beta)$ is time transformation in dependence on x . We consider the following model for degradation process under covariates:

$$Z(t|x) = Z(f(t, x, \beta)).$$

The covariates have double influence on the distribution of the first traumatic failure component: via degradation and directly. So we combine the AFT and the proportional hazards models:

$$S_1^{(tr)}(t|x, Z) = \exp \left\{ - \int_0^t e^{\beta T x(u)} \lambda(Z(u|x)) du \right\}.$$

Let us denote by

$$\begin{aligned} S^{(tr)}(t|x, Z) &= P(T^{(tr)} > t|x(u), \\ &\quad Z(u|x), 0 \leq u \leq t), \\ \lambda^{(tr)}(t|x, Z) &= - \frac{d}{dt} \ln S^{(tr)}(t|x, Z) \end{aligned}$$

the conditional distribution function and the failure rate of the traumatic failure given the covariates and the degradation.

So we consider the following *failure time-degradation covariate model*:

$$\begin{aligned} \lambda^{(tr)}(t|x, Z) &= e^{\beta T x(t)} \lambda(Z(f(t, x, \beta))) \\ &\quad + e^{\gamma T x(t)} \mu(f(t, x, \gamma)). \end{aligned}$$

Under this model,

$$\begin{aligned} S^{(tr)}(t|x, Z) &= \mathbf{P}(T^{(tr)} > t|x(u), \\ &\quad Z(u|x), 0 \leq u \leq t) \\ &= \exp \left\{ - \int_0^t e^{\beta T x(u)} \lambda(Z(u|x)) du - H(f(t, x, \gamma)) \right\}, \\ H(t) &= \int_0^t \mu(u) du. \end{aligned}$$

Let $T = \min(T^{(0)}, T^{(tr)})$ be the time of the unit failure. The survival function of the failure time T under the covariate x is

$$\begin{aligned} S(t|x) &= \mathbf{P}(T > t|x) = ES(t|x, Z), \\ S(t|x, Z) &= 1_{\{Z(t|x) < z_0\}} S^{(tr)}(t|x, Z). \end{aligned}$$

In particular, if $z_0 = \infty$, the survival functions $S(t|x, Z)$ and $S^{(tr)}(t|x, Z)$ coincide. Mean failure time under the covariate x is

$$\begin{aligned} e(x) &= \mathbf{E}(T|x) = \mathbf{E}(\mathbf{E}(T|x, Z)), \\ \mathbf{E}(T|x, Z) &= \int_0^{g(h(z_0), x, \beta)} S(t|x, Z) dt. \end{aligned}$$

The probability of nontraumatic failure under the covariate x in the interval $[0, t]$ is given by

$$\begin{aligned} P^{(0)}(t|x) &= \mathbf{E}P^{(0)}(t|x, Z), \\ P^{(0)}(t|x, Z) &= 1_{\{Z(t|x) \geq z_0\}} S(g(h(z_0), x, \beta)|x, Z). \end{aligned}$$

In particular, the probability of nontraumatic failure under the covariate x in the interval $[0, \infty)$ is obtained. The probability of traumatic failure under the covariate x in the interval $[0, t]$ is

$$\begin{aligned} P^{(tr)}(t|x) &= \mathbf{E}P^{(tr)}(t|x, Z), \\ P^{(tr)}(t|x, Z) &= 1 - S(t \wedge g(h(z_0), x, \beta)|x, Z). \end{aligned}$$

Analyzing failure time-degradation data requires not only the related probability of failures with degradation and covariates but also models for degradation process. The most-applied stochastic processes describing degradation are general path models and time-scaled stochastic processes with stationary and independent increments such as the γ -process, shock processes, and Wiener process with a drift:

General Path Models

$Z(t) = g(t, A, \theta)$, where g is a deterministic function and $A = (A_1, \dots, A_s)$ is a finite-dimensional random vector and θ is a finite-dimensional nonrandom parameter. The form of the function g may be suggested by the form of individual degradation curves. The degradation under the covariate x is modeled by

$$\begin{aligned} Z(t|x) &= g(f(t, x, \beta), A), \\ m(t|x) &= E g(f(t, x, \beta), A). \end{aligned}$$

Methods of estimation from degradation data are given in Ref. 3. Bagdonavičius *et al.* [18] considered estimation from failure time-degradation data.

Time-Scaled γ Process

$Z(t) = \sigma^2 \gamma(t)$, where $\gamma(t)$ is a process with independent increments such that for any fixed $t > 0$,

$$\gamma(t) \sim G(1, v(t)), v(t) = \frac{m(t)}{\sigma^2},$$

that is, $\gamma(t)$ has the γ distribution with the density

$$p_{\gamma(t)}(x) = \frac{x^{v(t)-1}}{\Gamma(v(t))} e^{-x}, \quad x \geq 0,$$

where $m(t)$ is an increasing function. Then,

$$Z(t|x) = \sigma^2 \gamma(f(t, x, \beta)).$$

The mean degradation and the covariances under the covariate x are

$$\begin{aligned} m(t|x) &= \mathbf{E}(Z(t|x)) = m(f(t, x, \beta)), \\ \mathbf{Cov}(Z(s|x), Z(t|x)) &= \sigma^2 m(f(s \wedge t, x, \beta)). \end{aligned}$$

Bagdonavičius and Nikulin [4,19] considered estimation from failure time-degradation data. Padgett and Tomlinson [20] considered estimation from degradation data.

Time-Scaled Wiener Process with a Drift

$Z(t) = m(t) + \sigma W(m(t))$, where W denotes the standard Wiener motion, that is, a process with independent increments such that $W(t) \sim N(0, t)$. Then,

$$Z(t|x) = m(f(t, x, \beta)) + \sigma W(m(f(t, x, \beta))).$$

The mean degradation and the covariance under the covariate x are

$$\begin{aligned} m(t|x) &= m(f(t, x, \beta)), \\ \mathbf{Cov}(Z(s|x), Z(t|x)) &= \sigma^2 m(f(s \wedge t, x, \beta)). \end{aligned}$$

Several authors [15,16,20,21] considered estimation from degradation data.

Shock Processes

Assume that degradation results from shocks, each of them leading to an increment of degradation. Let $T_n, (n \geq 1)$ be the time of the n th shock and X_n the n th increment of the degradation level. Let us denote by $N(t)$, the number of shocks in the interval $[0, t]$. Set $X_0 = 0$. The degradation process is given by

$$Z(t) = \sum_{n=1}^{\infty} 1\{T_n \leq t\} X_n = \sum_{n=0}^{N(t)} X_n.$$

Kahle and Wendt [17] model T_n as the moments of transition of the doubly stochastic Poisson process, that is, they suppose that the distribution of the number of shocks up to time t is given by

$$\mathbf{P}\{N(t) = k\} = \mathbf{E} \left\{ \frac{(Y \eta(t))^k}{k!} \exp \{-Y \eta(t)\} \right\},$$

where $\eta(t)$ is a deterministic function and Y is a nonnegative random variable with finite expectation. If Y is nonrandom, N is a nonhomogeneous Poisson process, in particular, when $\eta(t) = \lambda t$, N is a homogeneous Poisson process. If $\eta(t) = t$, then N is a mixed Poisson process. Other models for η may be used; for example, $\eta(t) = t^\alpha, \alpha > 0$. The random variable Y is taken from some parametric class of distributions.

Kahle and Lehmann [22] and Kahle and Wendt [27] considered parametric estimation from degradation data; Lehmann [16] considered estimation from failure time-degradation data; Harlamov [23] discusses inverse γ -process as a wear model; Zacks [24] gives failure distributions associated with general compound renewal damage processes. Bagdonavičius and Nikulin [4,19] considered the problem of estimation in accelerated degradation models, refer also to Nikulin *et al.* [25].

ACCIDENT PRECURSORS AND WARNING SYSTEMS MANAGEMENT: A BAYESIAN APPROACH TO MATHEMATICAL MODELS

ELISABETH PATÉ-CORNELL

Department of Management Science and
Engineering, Stanford University,
Stanford, California

THE IMPORTANCE OF PRECURSORS AND THE DIFFICULTY TO MONITOR THEM

Many accidents are preceded by near misses and/or precursors. Of course, in hindsight, they often could have been predicted and something should have been done in time to prevent a failure or reduce the risk. It is indeed a rare disaster that in retrospect did not involve a signal that is easy to identify after the fact and should have been detected earlier. One problem is that many such signals and near misses occur without significant consequences, and that organizations cannot always stop operations because someone has observed an unusual and troublesome event. Another problem is that in retrospect, it is easy to see why and how the accident and the signal were correlated but estimating the risk before the fact is much more problematic [1,2]. One key issue is to structure the hazard warnings to permit proper response [3]. The questions are thus first, how to monitor what most needs to be, and second how to assess the probability of an event (accident, disaster, of given severity) given the observation of such a signal. The next question is how to respond to a signal, sometimes with some lead time, sometimes immediately, given the costs and the benefits of different risk-reduction measures.

Identification and reporting of precursors through monitoring systems, and interpretation of the signal has been implemented in several industries, for example, the aviation reporting system [4,5]; in the nuclear power

industry, the sequence of status reports on precursors to potential severe core damage accidents [6–8] and the USNRC accident sequence precursor program [9,10]; and in the chemical industry, near miss management systems [11]. Also in the chemical industry, it was shown that accidents reoccur for similar reasons, and that observable disruptions can provide useful warnings [12]. Finally, in the context of storage of flammable gas, Zhou *et al.* [13] studied the dynamics of warnings based on the analysis of real-time risk data.

Precursors come in several forms. Signals can be observed through systematic reporting of near misses [14]. They can also be picked up by chance and indeed, by surprise. For example, an unknown terrorist group may appear to try to stage an attack, or a known technical system may threaten to fail in ways that were not anticipated. This is similar to finding by chance a needle in haystack. The problem is then to determine the significance of the signal, and the implications of that new piece of information in order to follow up if it is justified. This may entail collecting additional information that may either confirm or negate various hypotheses.

Third, one can observe near misses under the form of incomplete accident sequences; for example, an employee may have come close to derailing a train by excessive speed in a dangerous area. The repetition of such events can confirm the existence of a problem. The Concord supersonic aircraft, for instance, experienced more than 50 hits of its fuselage by pieces of tires that had blown up at take off, before such an event caused a tank rupture and a plane crash in 2000 [15]. In that case also, one can learn from a near miss by asking what was the probability of a full-fledged accident given what happened? And what should have been done to prevent it?

Fourth, through the direct monitoring of a continuous dynamic process, one can observe clearly, for example, how close one is from an event such as a flood by watching the level of water in a rising river. Given how fast the

process evolves and how much time one has to react when the hazard level exceeds different thresholds of threat, one can identify an alert threshold that would strike a balance between the lead time for protective actions and the probability of a false alert.

Precursors thus provide important information for risk management [16–19]. They are mostly useful when looking ahead to decide what to do to mitigate the risk, although observations of signals prior to an accident are often used in retrospect to find the root cause of a problem and/or assign the blame.

Relying on signals to take safety measures generally requires managing a trade-off between the probabilities of false positives and false negatives [20]. Classical statistics can provide an approach to the analysis of precursors [21,22] but they require data samples of sufficient size and a stable underlying condition that may not exist. Bayesian methods, by contrast rely on all existing information, which is updated given new data [23]. The use of these methods has been explored in the context of signals and precursors as an improvement over classical statistics [24]. They have also been described in the context of intelligence analysis [25], and counterterrorism [26,27].

What is described in this article relies in general on a probabilistic Bayesian method of precursor signal analysis in the context of a decision, which permits best observation and response [28–30]. The data then become input in a rational decision analysis [31] for risk management. This implies that the organization itself must be equipped to identify, communicate, and act upon warning signals [32–36]. The culture of the organization is thus a key factor in its ability to process such signals [37]. In designing a warning system, the main decisions are therefore which systems or process to monitor, what specific signals to observe, how to interpret the results, how to communicate the warnings, and how to best use the lead time that they provide. The fundamental issue is thus to set up an organizational warning system to observe and communicate appropriate signals. Confidentiality in reporting system is often an important success factor [38]. On

the one hand, one needs to filter out signals that do not require immediate attention so as not to swamp potential decision makers under lots of less relevant facts. On the other hand, filtering out relevant signals can be catastrophic as was, for example, the decision of FBI managers to ignore pre 9/11 signals that a number of people were taking suspect training in airplane operations.

In the end, the value of a warning or alert lies in the possibility that it may affect risk management decisions for the better. The concept of value of information [39] is thus central to the analysis of uncertainties about a signal, and the benefits of observation, analysis and response. That concept itself has its foundations in decision analysis and requires both a probabilistic assessment and an evaluation of the different possible outcomes given each option. This article describes a general probabilistic approach to the interpretation of signals in the context of risk management decisions, and presents examples based on Bayesian treatment of that information.

In the first part of the article, the importance of signals of a specific subsystem's malfunction is captured using a probabilistic risk analysis (PRA) of the overall system [40,41]. The analysis is extended to include human errors and thus signals that specific mistakes have taken place, along with their potential implications. A general model of optimization of a warning system is then presented, based on an explicit formulation of the trade-off between type I and type II errors. Finally, the principles of design and implementation of an organizational warning system are described.

PROBABILISTIC ANALYSIS OF WARNING SIGNALS

The principle behind the probabilistic analysis of a piece of information, such as a signal that something may be going wrong, is to separate the prior probability or base rate of the event (accident, catastrophe, disaster) and the quality of the signal. The prior probabilities of such events are provided by the information gathered so far, including performance statistics, test results, and expert

opinions. The quality of a precursor (signal, test, monitoring results, etc.) is described by the probabilities of false positives and false negatives, or put another way, the sensitivity (probability of true positive) and the specificity (probability of a true negative) of the test.

Noting E the adverse event that one is trying to avoid, S the signal that is observed, and NE or NS the negation of the event of the signal, the probability of an event *given* the signal ($p(E|S)$)¹ can be written using Bayes theorem and the total probability theorem:

$$\begin{aligned} p(E|S) &= p(E \text{ and } S)/p(S) \\ &= p(E)p(S|E)/[p(E \text{ and } S) + p(NE \text{ and } S)] \\ &= p(E)p(S|E)/[p(E)p(S|E) + p(NE) \\ &\quad \times p(S|NE)]. \end{aligned}$$

To describe the probabilities of errors, one can write that $p(S|E)$ is $1 - p(NS|E)$, where $p(NS|E)$ is the probability of a false negative and $p(S|NE)$ is the probability of a false positive defined per time unit or operation.

This formulation again allows separation of the characteristics of the event ($p(E)$) and of the quality of signals and of the performance of their sources (captors, sensors, human information, etc.).

The denominator $p(S)$, which is sometimes considered a mere “normalization factor,” is actually important because it requires that the analyst envision the possible cases in which the signal could be observed with or without the considered event. In the case of an intelligence system, for example, it requires constructing a structured set of scenarios that would yield the same information under different hypotheses.

¹As in classic probability notations, the vertical bar in $p(X|Y)$ means: probability of X *conditional* on Y or *given* Y, the comma in $p(X,Y)$ means joint probability of X and Y. The negation of X is noted here NX and $p(NX)$ means probability of NOT X, which is $1 - p(X)$.

Numerical Illustration

Assume a case in which the prior probability (base rate) of event E is 1/100 per year, where a signal S of E can be observed with a probability of false positive of 0.05 per year, and where the probability of a false negative is 0.01 given that E is going to occur. The formula above yields the probability of the event given the signal, which is 0.165 (16.5% chance of occurrence). Even though the signal occurred, it is still low because the prior of 1/100 is low.

Several Signals

The same type of analysis applies to the case where several signals can be observed. These signals may be conditionally dependent on the event, for example, because they come from the same source or related sources of information. The signals that are most significant are conditionally independent, that is, independent given the event. In general, however, even these signals are marginally dependent given an occurrence of the event to which they are both correlated. In addition, there can be further dependences if they are correlated not only by the occurrence of the event of interest but also by the source(s) of information. The probabilistic analysis of several signals thus encompasses all these possible dependence aspects. It relies on an extension of Bayes theorem, and in the general case can be expressed as

$$\begin{aligned} p(E|S_1 \text{ and } S_2) &= p(E \text{ and } S_1 \text{ and } S_2)/p(S_1 \text{ and } S_2) \\ &= p(E)p(S_1 \text{ and } S_2|E)/[p(E \text{ and } S_1 \text{ and } S_2) \\ &\quad + p(NE \text{ and } S_1 \text{ and } S_2)] \\ &= p(E)p(S_1|E)p(S_2|S_1 \text{ and } E)/ \\ &\quad [p(E)p(S_1|E)p(S_2|S_1 \text{ and } E) \\ &\quad + p(NE)p(S_1|NE)p(S_2|S_1 \text{ and } NE)]. \end{aligned}$$

In the case where S_1 and S_2 are conditionally independent, this formula can be simplified because $p(S_2|S_1, E)$ is equal to $p(S_2|E)$ and $p(S_2|S_1, NE)$ is equal to $p(S_2|NE)$. Therefore,

$$\begin{aligned}
p(E|S_1, S_2) &= p(E \text{ and } S_1 \text{ and } S_2) / p(S_1 \text{ and } S_2) \\
&= p(E) p(S_1 \text{ and } S_2 | E) / [p(E \text{ and } S_1 \text{ and } S_2) \\
&\quad + p(NE \text{ and } S_1 \text{ and } S_2)] \\
&= p(E) p(S_1 | E) p(S_2 | E) / \\
&\quad [p(E) p(S_1 | E) p(S_2 | E) \\
&\quad + p(NE) p(S_1 | NE) p(S_2 | NE)].
\end{aligned}$$

For an example of conditional dependence or independence of two signals, consider two weather predictions for the same place and the same day. If one is based on a satellite picture and the other on the arthritic pains of an individual who has linked them to the weather patterns, the signals seem to be independent given the weather (but generally correlated by the weather). If both predictions are generated from two photographs from the same satellite, they may be correlated not only by the weather itself but also by characteristics of the satellite's performance.

USING A PROBABILISTIC RISK ANALYSIS (PRA) TO IDENTIFY POTENTIAL PRECURSORS

One way to identify signals of possible malfunctions in large complex systems (including accidents that have not happened yet) is to use a PRA to identify the elements of accident scenarios. PRA [40,41] is based on a systematic identification of the failure modes of a system, structured into a set of exhaustive, mutually exclusive scenarios. If a minimum set of events that lead to a failure ("min-cut set") is not completed, the system does not fail but the subset of a failure mode event(s) that have occurred can be regarded as a near miss. For instance, if an aircraft operates on four jet engines but can work with a single one, failure of the four is a failure mode (leading to a crash) and failures of one, two, or three jet engines are near misses, the last one being the closest call.

More importantly perhaps, PRA allows computing the probability of a system failure given the occurrence of some basic component failures. One can thus use that analytical

framework to compute the probability of a failure given the unfolding of a partial accident scenario (failure mode, "min-cut set"), or given the deterioration of components.

Failure of a Redundancy in a Subsystem of Parallel Components

Consider an electric system with two generators in parallel, or a cooling system with several tanks in parallel. If one fails, the system still works but the probability of failure has become higher with the loss of one of the redundant elements. The failure probability may become very high, especially if the failures of the redundant elements are dependent. One can use a PRA to compute how close one then is to system failure.

Assume, for instance, that the failure modes (sets of events leading to system failure) have been identified as $M_1, M_2, M_3, \dots$. According to the total probability theorem, the probability of system failure as a function of that of the failure modes is

$$\begin{aligned}
p(F) &= \sum_i p(M_i) - \sum_{ij} p(M_i, M_j) \\
&\quad + \sum_{ijk} p(M_i, M_j, M_k) - \dots
\end{aligned}$$

Given that the failure mode M_i , for example, has not been completed, but that a subset $M_{i'}$ of the events that constitute M_i has been observed (e.g., failure of one out of two redundant elements), one can write the $p(F)$ given $M_{i'}$ conditioning the above equation on the occurrence of $M_{i'}$:

$$\begin{aligned}
p(F|M_{i'}) &= \sum_i p(M_i|M_{i'}) - \sum_{ij} p(M_i, M_j|M_{i'}) \\
&\quad + \sum_{ijk} p(M_i, M_j, M_k|M_{i'}) - \dots
\end{aligned}$$

$M_{i'}$ is a "near miss" but how close to an actual failure $M_{i'}$ has taken the system can thus be computed using this formula.

Numerical Illustration

Consider a system (Fig. 1) that has three subsystems in series, one of which is made of two components in parallel.

Figure 1. Simple system of three subsystems in series, one of which has two components in parallel.

Assume that the failures of 1.1 and 3.1 are independent of all others, that there is a dependence only between the failures of 2.1 and 2.2, and that the failure probabilities of the components per time unit or operation are

$$p(1.1) = 10^{-3}$$

$$p(2.1) = 10^{-2}$$

$$p(2.2|2.1) = 0.5$$

$$p(3.1) = 10^{-2}$$

$$\begin{aligned}
 p(F) &= p(1.1) + p(2.1)p(2.2|2.1) + p(3.1) \\
 &\quad - \Sigma p(\text{two failure modes}) \\
 &\quad + p(\text{three failure modes}).
 \end{aligned}$$

The failure of 2.1 can be considered a close call (near miss) because the probability of system failure is then

$$p(F|2.1) = p(1.1) + p(3.1) + p(2.2|2.1) \approx 0.511.$$

At that point, the safety of the system relies in large part on the performance of the redundant component. The risk manager has to strengthen it immediately and/or replace 2.1. If possible, dependences among failures of redundant systems should be reduced or eliminated. In the future, lessons should be drawn, in particular, from near misses involving human errors, in which case a critical mistake that affect several components can bring the system close to failure.

Increase of System Failure Probability by Weakening of a Component

Another precursor to system failure is the weakening of one of its components. PRA allows computing the probability of system failure given the increase of component failure probability. It can also guide the schedule, extent, and priorities of inspection and maintenance of the different subsystems and components according to their contribution to the system failure risk. An example is that of the heat shield of the space system. A weakening of the tiles or panels that protect the edges of the wings is an accident precursor. It can happen at take off, for example, under the impact of a piece of debris. It can happen in orbit, for instance, if the tiles are damaged during extravehicular activities. It can also happen if the tiles are poorly maintained and some bonds are weak. The following example shows the vulnerability of a mission to such weakening of the tiles.

Illustration: Effect of Errors in the Maintenance of the Space Shuttle Tiles

In 1986, the space shuttle Challenger exploded at liftoff due to a failure of the O-rings of the solid rocket boosters. Following that accident, NASA decided to do a number of PRAs to identify potential weak points of the system, and to try to address these problems before they cause another accident. In a study conducted at Stanford [42,43], a PRA was performed to assess the risks of shuttle failure due to a failure of the tiles of the orbiters' heat shield. Twenty-five thousand tiles protect the orbiter, each different from the other. The objective was to determine potential improvements of the tile maintenance given that weak bonds could become accident precursors. There are two main failure modes. The first one is a debris hit that causes tiles to debond. The second one involves debonding of a tile under regular loads (e.g., vibrations) because the tile capacity has been decreased. This can be caused, for example, by poor bonding of the tile during maintenance, which, in turn, can be the result of organizational factors, for example, excessive time constraints. After

a tile debonds, the adjacent ones at reentry are subjected to additional heat loads due to turbulences in the cavity. Hot gases can then enter the structure and damage critical subsystems under the orbiter's skin causing a catastrophic accident. The model was structured using four parameters that are characterized for each tile as a function of its location on the surface: the density of debris hits at that place that had been observed in previous missions, the aerodynamic forces (that contribute to the loss of adjacent tiles), the heat load, and the criticality level of the subsystems under the aluminum skin.

Figure 2 shows the influence diagram that was used in the study to compute the resulting probability of losing a shuttle because of a failure of the tiles.

The first results of the study were presented as a view of the orbiters' underside in which each zone was shaded as a function of the contribution of each tile to the overall failure probability (Fig. 3). The contribution of tile failure to the overall probability of a shuttle accident was found to be in the order of 10% of the overall mission failure probability

(10^{-3} per flight for an overall probability of accident in the order of 10^{-2}).

Warnings and Signals

Some weak bonds could be detected by manual inspection of the bond. Because this task was long and delicate, the prioritization of the tiles in terms of system vulnerability was essential.

But the 1990 study provided a warning of things to come, that is, the 2003 Columbia accident, where a piece of debris at take-off opened a gap in the heat shield [44]. An important part of the study results was the fact that debris hits contributed about half of the risks of losing an orbiter due to tile failure. Some possible debris trajectories had been computed at Johnson Space Center. Backtracking these trajectories from the more risk critical parts of the orbiter to their potential sources revealed that a critical part of the risk was attributable to the insulation of the external tank. The bonding of that insulation was weakened, in particular, by the attachment of a fuel line along the tank surface. Pieces of the tank insulation could

Figure 2. Structure of the risk assessment model for the loss of a shuttle mission due to loss of tiles. (Source: From Ref. 43).

Figure 3. Results of the study of the space shuttle tile failure risks. (Source: From Ref. 43).

then hit the wings of the orbiter (and small ones had hit the tiles before). This was a signal that more attention needed to be given to the insulation of the external tank. This failure mode was identified in as a priority in risk management in spite of the fact that failure of the heat shield had not yet caused an accident (only two tiles had been lost in flight prior to the 1990 study). There was some attempt by NASA to address the problem, but, obviously, the response was

not satisfactory. In 2003, the Columbia space shuttle exploded in flight because a piece of debris from the insulation of the external tank had hit the reinforced carbon-carbon panels that protected the leading edge of a wing.

Human Errors as Accident Precursors: Observation in the PRA Context

Human errors that have been observed without causing an accident can be considered

useful precursors. In operating rooms, they include wrong intubation of the patient (ventilating the stomach instead of the lungs) or wrong dosage of an anesthetic [48]. The question is how close a call it was, what should be the response, and how urgent it is. The problem is to link these human errors to the probabilities of accident sequences. But to derive some risk management conclusions, one then needs to relate human errors to the alertness and competence of the anesthesiologists and to the relevant management factors such as hiring and training. One can then decide what action to take to monitor the performance of the physicians in charge.

Organizational factors are often part of the root causes of industrial accidents and system failures. For example, Grabowski *et al.* [45] propose an approach to developing leading risk indicators in virtual organizations. Identifying accident sequences, precursors, and the effectiveness of risk management measures can be achieved through a probabilistic analysis of the whole system such as the systems–action–management (SAM) model presented in Fig. 4 [46]. The bottom part represents the PRA for the system, for instance the influence diagram of Fig. 2. The level above represents the decisions and actions of the people directly involved, for example the

maintenance technicians in charge of replacing damaged tiles. One error that can appear here is that a technician may decide to take a shortcut in cleaning the cavity before bonding a new tile, thus weakening the bond. In turn, that decision may be influenced by the decision of the management to impose strict deadlines and a daily quota of tiles to be maintained, when a bit more flexibility (e.g., a weekly quota) might avoid the temptation of a shortcut. In another illustration of the SAM model, one can focus on the probability that a ship (e.g., an oil tanker) lose propulsion, hits the ground causing a breach in the hull, and spills oil in the sea. The loss of propulsion itself may be attributable to a problem of design or maintenance, and the grounding to control of the drift by the crew, location, weather, and speed at the time of the incident, and the source term (amount of oil released) to the design of the hull (e.g., single vs double hull). All these factors depend in turn on management decisions, involving resource allocation and personnel management. The SAM model allows connecting these decisions to the risk of an oil spill knowing the ship's routes. A breach in the hull is thus an immediate precursor to the oil spill but the training and the coherence of the crew are thus early signal of their ability to cope with an incident.

Figure 4. The structure of the systems–actions–management model that links technical PRA to human decisions (and errors) to management decisions.

The SAM model thus allows assessing the probability of a full-fledged accident given a close call from a human error. Furthermore, it allows identifying the management factors that can be improved to decrease the probability that it happens, and to make those choices based on the costs and the risk-reduction benefits of these measures.

Anesthesia Patient Risks

Human errors have been recognized for a longtime as a risk factor in medicine [47] where observing, diagnosing, and acting upon precursors of accident sequences is critical. An example of precursor involving human and organizational factors is found in the case of an analysis of anesthesia patient risk (Fig. 5). That study [48] was based first on statistical data about the precursors, that is, the initiating events that start an accident sequence. We also had statistics about mortality in anesthesia accidents. We needed to model the dynamics of accident scenarios in between to use this model in risk assessment and risk management.

From the probability of the precursors (e.g., of a tube disconnect), one could then compute the probability that the corresponding signal is observed, that the diagnosis of the problem is made and a proper solution is found, and that the patient recover given that oxygen deprivation can cause a serious injury or death within minutes depending on the characteristics of the patient.

This is another case in which the immediate observation of and reaction to precursors is essential in risk management, but also where precursors regarding the incompetence or the alertness problems of a practitioner constitute real warnings that something needs to be addressed before an accident occurs.

Challenges of Linking Occurrences of Signals and a Probabilistic Risk Analysis Model

All signals may not fit neatly and obviously in the framework of the PRA for a given system [see, for example, the chapter on ASP by Sattison [10]]. What is clear is that for the system to fail, one or more of the failure modes must take place. So the general equation linking occurrences of signals to the probabilities of the failure modes and of system failure can be written as

$$p(F|S) = \sum_i p(M_i|S) - \sum_{ij} p(M_i \text{ and } M_j|S) + \sum_{ijk} p(M_i \text{ and } M_j \text{ and } M_k|S) - \dots$$

What may be less clear are the links between the failure modes (and their factors) and the occurrence of a signal ($p(M_i|S)$, $p(M_i, M_j|S)$, ...). For instance, a human error such as the deterioration of the performance of a maintenance crew, which may seem removed from the system's safety, may affect

Figure 5. Structure of a dynamic model for the analysis of anesthesia patient risks: SA_j , state of the anesthesiologist (level of alertness and competence); $p(IE_i)$, probability of the initiating event IE_i ; $p(AA|IE_i)$ probability of an anesthesia accident given an initiating event; Ok, organizational factors and risk management measures that influence the state of the anesthesiologist.

a chain of events, resulting in the increase of the probability of failure more than intuition suggests. The importance of a change in external loads, such as a change in the climate that increases the probability of severe storms and may affect several components, may not be immediately recognized. In other cases, a minor deterioration of an external system—for example, a small change in the reliability of the electric grid—may increase the failure risk. One can find many other instances in which the PRA model does not yield immediately the variation of the failure probability given the signal. The problem is generally case-specific and the value of the result depends on the ability of the analyst to identify the existence of the link between the signal and the system's performance, and to gather and use relevant information.

A STRING OF MISSED PRECURSORS AND SIGNALS

Neglecting Repeated Identical Problems because They Have Not Caused a Disaster Yet

One problem when no accident happens in a string of similar near misses is that these events can be considered neglected (and underestimated as survivable) when, in fact, the probability of catastrophic failure may be high and randomness and luck are deceitful.

An example of that phenomenon is the sequence of missed precursors that preceded the crash of the supersonic plane Concorde in 2000. After about 75,000 flights, 57 tires had burst at takeoff without critical damage to the aircraft. The problem was the need for long runways given the shape of the plane, and the danger of heating and bursting given the technology of the tires. Their rubber surface was divided into lozenges. These tires had split with bursts, hitting the under surface of the aircraft, but for a while missed the fuel tanks, until they pierced the fuselage and the tank in an accident that occurred at takeoff in July 2000. By then it should have been clear that the probability of such a disaster was high by aviation safety standards but the fear was that fixing that problem might create another one. It seems that the balance of risks was not properly considered.

This is typical of cases where the evidence is clear and the fact that no accident has happened causes the complacency of the organization. The likelihood of a hit causing a fuel tank rupture could have been computed based on observations of trajectories and patterns, and a crash could have avoided. The argument that is sometimes heard when such luck allows avoiding a disaster for a while can be called the *zillion-mile argument*: we are safe because we have survived these incidents in the past. In cases like this, one can sometimes point to the gap between the safety-first discourse and the reaction to precursors. Because it is true that organizations cannot react to all remotely possible events, an analysis of the probabilities of a disaster can be very useful in interpreting the precursors and their predictive values in probabilistic terms.

Failure to Monitor a System and to Detect a Serious Problem

Some clear signals are not always properly monitored by the organizations responsible for a system. This was the case, for example, in the Ford Firestone fiasco in which the failure of Firestone tires (by tread separation) on Ford vehicles caused many rollovers resulting in more than 250 deaths and 3000 serious injuries. The problem was apparently detected in the end by insurance companies but after much time had been lost. Ford Motor Company then decided to set up a report system that would bring all incidents to the attention of the company's executive. This is one example of what is described below as an "organizational warning system." Such a system, however, has to provide channels to communicate warnings to the appropriate decision maker(s). It also has to include some filtering so that the system is not clogged with false alerts, which are costly not only because of the time and production lost but also because people start losing confidence in the system itself and may stop responding to signals.

Another case where such an organizational warning system is essential is the monitoring of medical devices once they are released on the market—given the nature of these devices (e.g., cardiac), the uncertainty

that remains once they are approved (offlabel uses, unusual patients, vulnerability to the skills of the physicians). Postmarket monitoring needs to be set up so that the Food and Drug Administration is aware as soon as possible of problems of design, manufacturing, or use that require immediate adjustment. These signals were missed for a while in the case of the Guidant drug-eluting stents, which caused multiple accidents before being withdrawn from the market.

FILTERING SIGNALS: MANAGING THE TRADE-OFF BETWEEN TYPE I AND TYPE II ERRORS

One key problem in setting an early-warning system is to manage the trade-off between the probabilities and the consequences of false positives and false negatives, both linked to the sensitivity of the signal when it is observed. Consider here a continuous stochastic process representing the level at a given time of a potentially hazardous phenomenon (for instance, the density of smoke in a room or the level of a river that can overflow). Figure 6 illustrates the case of the risk of a fire with lethal smoke density or a flood from an overflow of a river.

The problem here has multiple dimensions. The question is to know where to set the alert level considering the trade-off between the lead time that the signal provides (the higher the threshold, the shorter the lead time) and the probability of a false alert that has costs in itself (e.g., evacuation) but also decreases the rate of response to the signal in the future. For each possible threshold level (here: $d(\Phi)$), one can compute for the given stochastic model, the upcrossing rate (the rate of alerts) some being false alerts and some true ones that permit reducing the losses given the lead time.

Implementing this method thus requires three types of models. The first one is a model of the underlying phenomenon (how often does it occur, how serious it is, and how fast does it evolve when it is a true alert). The second is a model of the response rate given the past history and the system's performance. It involves the human memory and the "cry-wolf" effect on the response, which obviously depend on the potential severity of the event and the costs of a response. The third model represents the effectiveness of the use of the lead time once the alert threshold has been exceeded, and therefore, the risk-reduction benefits (in probabilistic terms) of the warning system defined by that

Figure 6. Stochastic process and possible alert thresholds. (Source: From Ref. 20).

alert threshold. Given the benefits of the use of the lead time and the costs of the alert system, one can then compute an optimal threshold that maximizes either a benefit-cost ratio or a utility function, possibly including several attributes (human safety and property damage) and risk attitudes. Note that in this case, another way to proceed is simply to figure out the lead time that is needed (for instance, for the evacuation of a threatened region) and to back-figure the appropriate threshold of alert.

ORGANIZATIONAL WARNING SYSTEMS

Observing a worrisome signal somewhere in an organization is not always sufficient to ensure proper response. This was the case, for instance, of the FBI shortly before 9/11/01, when an agent had observed that potential terrorists were learning how to fly under suspect circumstances and tried to warn the hierarchy above her head, but her message was ignored.

The design of an organizational warning system requires addressing several problems. Communication channels first have to exist or to be set up. The message may get distorted along the communication lines, or simply ignored and blocked at a particular level of the hierarchy. The careful design of an organizational warning system thus requires first deciding what can possibly be the weak points of a system, and to ensure adequate monitoring of the corresponding signals. Second, transmission lines must be set up (sometimes with redundancies) so that the message reaches the appropriate decision maker. But sometimes, filtering has to occur to prevent clogging of the system, and sorting the signals requires a clear examination of the risks involved. The probabilities of false positives and false negatives are essential to a rational interpretation of the information and an assessment of the posterior probability of an event given what has been observed [36].

The organization thus has to ensure that someone will monitor potential problems and set up a communication system with incentives such that the message is communicated to the appropriate level. From a theoretical

point of view, these incentives have to be aligned (e.g., on the basis of a “principal-agent” model), so that the decision maker gets the story straight and that there be no attempt to punish the messenger.

The dynamics of system deterioration and the speed at which events unfold are critical: the organization has to respond on the spot to immediate threats, which sometimes requires a radical switch to a crisis mode. In any case, managing the trade-off between false positives and false negatives requires an implicit or explicit valuation of their probabilities and outcomes. Communicating the message effectively may involve a candid and accurate description of uncertainties, even if it seems to weaken the message.

CONCLUSIONS

Identifying, observing, and communicating precursors and their risk implications are essential parts of risk management. In retrospect, it is often easy after an accident to find that precursors could and should have been observed. In reality, and looking forward, the question is first to make sure that appropriate warning systems are in place and that the message will be adequately communicated. An unavoidable challenge when uncertainties exist is to assess and communicate the chances of possible outcomes. The value of the information provided by any warning lies in its ability to make timely and adequate decisions. There is often an unavoidable trade-off between the potential for false positives and false negatives. Managing this trade-off requires a value system based on risk attitudes, whether in private or public decisions.

ADVANCED BRANCHING PROCESSES

FLORIAN SIMATOS

Technology, Eindhoven,
Netherlands

INTRODUCTION

Branching processes have their roots in the study of the so-called family name extinction problem (see *Introduction to Branching Processes*) and find their most natural and important applications in biology, especially in the study of population dynamics. They were also motivated by the study of nuclear fission reactions and underwent rapid development during the Manhattan project under the impulse of Szilárd and Ulam. To date, they continue to be very important in reactor physics. They also play a major role in (applied) probability at large, and appear in a wide variety of problems in queuing theory, percolation theory, random graphs, statistical mechanics, the analysis of algorithms, and bins and balls problems, to name a few.

The appearance of branching processes in so many contexts has triggered the need for extensions and variations around the classical Galton—Watson branching process. For instance, their application in particle physics provided an impetus to study them in continuous time. The possible extensions are almost endless, and indeed new models of processes exhibiting a branching structure are frequently proposed and studied. Such models allow for instance time and/or space to be continuous, individuals to have one of several types, immigration to take place, catastrophes to happen, individuals to move in space, each individual's dynamic to depend on time, space, the state of the process itself or some exogenous resources, a combination of all these ingredients, and many more.

In this article, we focus more specifically on three advanced models of branching

processes: (i) branching processes in random environment, which are examples of branching processes, where the dynamic evolves (randomly) over time; (ii) branching random walks that exhibit a spatial feature; and (iii) continuous state branching processes (CSBPs) that can be seen as continuous approximations of Galton—Watson processes where both time and space are continuous. The presentation of CSBPs will also be a good place to briefly discuss superprocesses. We each time focus on the most basic properties of these processes, such as the extinction probability or the behavior of extremal particles.

This choice of topics does not aim to be exhaustive and reflects a personal selection of exciting and recent research on branching processes. It leaves out certain important classes of models, which include multitype branching processes, branching processes with immigration, and population-size-dependent branching processes. For multitype branching processes, the book by Mode [1] offers a good starting point. Branching processes with immigration were initially proposed by Heathcote [2,3] as branching models that could have a non-trivial stationary distribution. Lyons *et al.* [4] showed, via change of measure arguments, that they played a crucial role in the study of Galton—Watson processes. Finally, population-size-dependent branching processes, originally proposed by Labkovskii [5], find their motivations in population dynamics: they are elegant models that introduce dependency between individuals and can account for the important biological notion of carrying capacity, see for instance [6–8]. The interested reader can find more results in the extensive survey by Vatutin and Zubkov [9,10] that gathers results up to 1993 as well as in the recent books by Haccou *et al.* [11] and by Kimmel and Axelrod [12].

Before going on, recall (see *Introduction to Branching Processes*) that a Galton—Watson branching process $(Z_n, n \geq 0)$ is an $\mathbb{N}$ -valued Markov chain obeying to the following recursion:

$$Z_{n+1} = \sum_{k=1}^{Z_n} X_{ni}, \quad n = 0, 1, 2, \dots, \quad (1)$$

where the $(X_{ni}, n, i = 0, 1, 2, \dots)$ are independent and identically distributed (i.i.d.) random variables following the so-called *offspring distribution*. A Galton—Watson process is classified according to the value of the mean $m = \mathbb{E}(X_{ni})$ of its offspring distribution. If $m < 1$, the process is subcritical: it dies out almost surely, the survival probability $\mathbb{P}(Z_n > 0)$ decays exponentially fast at speed m^n , and Z_n conditioned on being non-zero converges weakly. If $m = 1$, the process is critical: it dies out almost surely, the survival probability $\mathbb{P}(Z_n > 0)$ decays polynomially fast, and Z_n conditioned on being non-zero grows polynomially fast. Finally, if $m > 1$, the process is supercritical: it may survive forever, and grows exponentially fast in the event $\{\forall n \geq 0 : Z_n > 0\}$ of survival.

BRANCHING PROCESSES IN RANDOM ENVIRONMENT

A first possible generalization of the Galton—Watson model allows for the offspring distribution to vary over time: then, the recursion (1) still holds, the X_{ni} s are still independent but the law of X_{ni} may depend on n . If π_{n+1} is the offspring distribution in generation n and $\Pi = (\pi_n)$, that is, π_{n+1} is the common law of the $(X_{ni}, i = 0, 1, 2, \dots)$ and Π is the environmental process, then this model defines a branching process in varying environment Π . We talk about branching process in random environment when the sequence Π is itself random and independent from Z_0 . Note that in this case, π_n is a random probability distribution on $\mathbb{N}$.

As always in the case of stochastic processes in random environment, one may follow two approaches for their study: (i) the quenched approach, which fixes a realization of the environment and studies the process in it; it is most natural from the point of view of the applications and (ii) the annealed approach, where the various characteristics of interest are calculated by averaging over the environment. For instance, the

extinction probability is a random variable in the quenched approach, and a deterministic number in the annealed approach.

When the environmental process is assumed to be stationary and ergodic, which includes for instance the case of i.i.d. environment or the case where the environment is a stationary Markov chain, it is known since the pioneering works of Smith [13], Smith and Wilkinson [14], and Athreya and Karlin [15,16] that the extinction problem and the description of the asymptotic growth have fairly general solutions. Although in the classical Galton—Watson case, the classification of Z_n is in terms of the mean of the offspring distribution, it is not difficult to see that in the case of random (stationary and ergodic) environment the mean of the logarithm of the mean is the meaningful quantity to look at. More precisely, if π is a probability distribution on $\mathbb{N}$, let $m(\pi) = \sum_y y\pi(\{y\})$ be its mean. Then, by definition (1), we have

$$\mathbb{E}(Z_n | \Pi) = Z_0 m(\pi_1) \cdots m(\pi_n) = Z_0 e^{S_n},$$

where we have defined

$$S_n = \log m(\pi_1) + \cdots + \log m(\pi_n).$$

By the ergodic theorem, we have $S_n/n \rightarrow \mathbb{E}(\log m(\pi_1))$ as $n \rightarrow +\infty$, which implies that $[\mathbb{E}(Z_n | \Pi)]^{1/n} \rightarrow \exp[\mathbb{E}(\log m(\pi_1))]$. In particular, conditionally on the environment, the mean of Z_n goes to 0 if $\mathbb{E}(\log m(\pi_1)) < 0$ and to $+\infty$ if $\mathbb{E}(\log m(\pi_1)) > 0$. This suggests to classify the behavior of Z_n in terms of $\mathbb{E}(\log m(\pi_1))$, and under some mild technical assumptions it holds indeed that Z_n dies out almost surely if $\mathbb{E}(\log m(\pi_1)) \leq 0$ (subcritical and critical cases) and has a positive chance of surviving if $\mathbb{E}(\log m(\pi_1)) > 0$ (supercritical case). More precisely, we have the following quenched result: if $q(\Pi)$ is the (random) extinction probability of Z_n given Π , then $\mathbb{P}(q(\Pi) = 1) = 1$ in the former case and $\mathbb{P}(q(\Pi) < 1) = 1$ in the latter case.

In the supercritical case $\mathbb{E}(\log m(\pi_1)) > 0$, there is an interesting technical condition that is both necessary and sufficient to allow the process to survive with positive probability: namely, in addition to $\mathbb{E}(\log m(\pi_1)) > 0$ one also needs to assume

$\mathbb{E}(-\log(1 - \pi_1(\{0\}))) < +\infty$. This condition shows the interesting interplay that arises between Z_n and the environment: even though $\mathbb{E}(\log m(\pi_1)) > 0$ is sufficient to make the conditional mean of Z_n diverge, if $\mathbb{E}(-\log(1 - \pi_1(\{0\}))) = +\infty$ then the process almost surely dies out because the probability of having an unfavorable environment is large, where by unfavorable environment we mean an environment π where the (random) probability $\pi(\{0\})$ of having no offspring is close to 1. In other words, if $\mathbb{E}(-\log(1 - \pi_1(\{0\}))) = +\infty$ then the process gets almost surely extinct because of the wide fluctuation of the environment.

The classification of Z_n into the subcritical, critical, and supercritical cases also corresponds to different asymptotic behaviors of Z_n conditioned on non-extinction (here again, we have the quenched results of Athreya and Karlin [15] in mind). In that respect, Z_n shares many similarities with a Galton—Watson process, although there are some subtle differences as we see at the end of this section. In the supercritical case, Z_n grows exponentially fast in the event of non-extinction, whereas in the subcritical case, Z_n conditioned on being non-zero converges weakly to a non-degenerate random variable. In the critical case, Z_n conditioned on being non-zero converges weakly to $+\infty$, a result that can be refined in the case of i.i.d. environment.

Indeed, the case where the (π_i) are i.i.d. has been extensively studied. In this case, S_n is a random walk and recent works have highlighted the intimate relation between Z_n and S_n . In particular, the classification of Z_n can be generalized as follows. It is known from random walk theory that, when one excludes the trivial case where $S_n = S_0$ for every n , there are only three possibilities concerning the almost sure behavior of (S_n) : either it drifts to $-\infty$, or it oscillates with $\liminf_n S_n = -\infty$ and $\limsup_n S_n = +\infty$, or it drifts to $+\infty$. Then, without assuming that the mean $\mathbb{E}(\log m(\pi_1))$ exists, Z_n can be said to be subcritical if $S_n \rightarrow -\infty$, critical if S_n oscillates, and supercritical if $S_n \rightarrow +\infty$. Within this terminology, Afanasyev *et al.* [17] studied the critical case and were able to obtain striking results linking the behavior of Z_n to

the behavior of its associated random walk. In particular, this work emphasized the major role played by fluctuation theory of random walks in the study of branching processes in random (i.i.d.) environment, a line of thought that has been very active since then.

Let us illustrate this idea with some of the results of Afanasyev *et al.* [17], so consider Z_n a critical branching process in random environment. As Z_n is absorbed at 0, we have $\mathbb{P}(Z_n > 0 \mid \Pi) \leq \mathbb{P}(Z_m > 0 \mid \Pi)$ for any $m \leq n$ and as Z_n is integer-valued, we obtain $\mathbb{P}(Z_n > 0 \mid \Pi) \leq \mathbb{E}(Z_m \mid \Pi)$. It follows that

$$\mathbb{P}(Z_n > 0 \mid \Pi) \leq Z_0 \exp \left(\min_{0 \leq m \leq n} S_m \right),$$

which gives an upper bound, in term of the infimum process of the random walk S_n , on the decay rate of the extinction probability in the quenched approach. It turns out that this upper bound is essentially correct, and that the infimum also leads to the correct decay rate of the extinction probability in the annealed approach, although in a different form. Indeed, it can be shown under fairly general assumptions that

$$\mathbb{P}(Z_n > 0) \sim \theta \mathbb{P}(\min(S_1, \dots, S_n) > 0) \quad (2)$$

for some $\theta \in (0, \infty)$. Moreover, conditionally on $\{Z_n > 0\}$, Z_n/e^{S_n} converges weakly to a random variable W , almost surely finite and strictly positive, showing that S_n essentially governs the growth rate of Z_n . Finally, although it is natural to consider the growth rate and extinction probability of the process Z_n , one can also reverse the viewpoint and study the kind of environment that makes the process survive for a long time. And actually, the conditioning $\{Z_n > 0\}$ has a strong impact on the environment: although S_n oscillates, conditionally on $\{Z_n > 0\}$ the process $(S_k, 0 \leq k \leq n)$ suitably rescaled can be shown to converge to the meander of a Lévy process, informally, a Lévy process conditioned on staying positive. This provides another illustration of the richness of this class of models, where the interplay between the environment and the process leads to very interesting behavior.

These various results concern the annealed approach: Equation (2) is for

instance obtained by averaging over the environment. However, the connection between Z_n and S_n continues to hold in the quenched approach. In Ref. 18, it is for instance shown that Z_n passes through a number of bottlenecks at the moments close to the sequential points of minima in the associated random walk. More precisely, if $\tau(n) = \min\{k \geq 0 : S_j \geq S_k, j = 0, \dots, n\}$ is the leftmost point of the interval $[0, n]$ at which the minimal value of $(S_j, j = 0, \dots, n)$ is attained, $Z_{\tau(n)}$ conditionally on the environment and on $\{Z_n > 0\}$ converges weakly to a finite random variable. For further reading on this topic, the reader is referred to Refs 19 and 20.

Let us conclude this section by completing the classification of branching processes in random environment. We have mentioned that similarly as Galton—Watson processes, branching processes in random environment could be classified as subcritical, critical, or supercritical according to whether $\mathbb{E}(Y) < 0$, $\mathbb{E}(Y) = 0$, or $\mathbb{E}(Y) > 0$, with $Y = \log m(\pi_1)$ (in the “simple” case where Y is indeed integrable). Interestingly, assuming that $\mathbb{E}(e^Y)$ is finite for every $t \geq 0$, the subcritical phase can be further subdivided, according to whether $\mathbb{E}(Ye^Y) > 0$, $\mathbb{E}(Ye^Y) = 0$, or $\mathbb{E}(Ye^Y) < 0$ corresponding respectively, in the terminology of Birkner *et al.* [21], to the weakly subcritical, intermediate subcritical, and strongly subcritical cases. These three cases correspond to different speeds of extinction: in the weakly subcritical case, there exists $\beta \in (0, 1)$ such that $\mathbb{E}(Ye^{\beta Y}) = 0$ and $\mathbb{P}(Z_n > 0)$ decays like $n^{-3/2}[\mathbb{E}(e^{\beta Y})]^n$; in the intermediate subcritical case, $\mathbb{P}(Z_n > 0)$ decays like $n^{-1/2}[\mathbb{E}(e^Y)]^n$; finally, in the strongly subcritical case, $\mathbb{P}(Z_n > 0)$ decays like $[\mathbb{E}(e^Y)]^n$. These decay rates are to be compared to the classical Galton—Watson process, wherein the subcritical case $\mathbb{P}(Z_n > 0)$ decays like m^n , corresponding to the strongly subcritical case, because when Y is determinist we have the relation $m = \mathbb{E}e^Y$.

Further reading on branching processes in random environment includes, for example, Refs 22 and 23 for the study of the subcritical case using the annealed approach, while the trajectories of Z_n under various conditionings, namely dying at a distant given moment

and attaining a high level, have been studied in Refs 24,25 and 26,27, respectively. In Ref. 28, the survival probability of the critical multitype branching process in a Markovian random environment is investigated.

BRANCHING RANDOM WALKS

Branching random walks are extension of Galton—Watson processes that, in addition to the genealogical structure, add a spatial component to the model. Each individual has a location, say for simplicity on the real line. Typically, each individual begets a random number of offspring, as in a regular branching process, and the positions of these children form a point process centered around the location of the parent. For instance, if $B = \sum_{x \in B} \delta_x$ is the law of the point process governing the locations of the offspring of a given individual, with δ_x the Dirac measure at $x \in \mathbb{R}$, the locations of the children of an individual located at y are given by the atoms of the measure $\sum_{x \in B} \delta_{y+x}$. Branching random walks can therefore naturally be seen as measure-valued Markov processes, which will turn out to be the right point of view when discussing superprocesses. Another viewpoint is to see branching random walks as random labeled trees: the tree itself represents the genealogical structure, whereas the label on an edge represents the displacement of a child with respect to its parent. Nodes of the tree then naturally inherit labels recursively, where the root is assigned any label, and the label of a node that is not the root is given by the label of its parent plus the label on the corresponding edge.

There is an interesting connection between branching random walks and (general) branching processes. In the case where the atoms of B are in $(0, \infty)$, particles of the branching random walk live on the positive half-line and their positions can therefore be interpreted as the time at which the corresponding particle is born. Keeping track of the filiation between particles, we see that within this interpretation, each particle gives birth at times given by the atoms of the random measure B . This is exactly the model of general, or Crump—Mode—Jagers,

branching processes (see *Introduction to Branching Processes*).

One of the most studied questions related to branching random walks concerns the long-term behavior of extremal particles. Of course, as the branching random walk is absorbed when there are no more particles, this question only makes sense when the underlying Galton—Watson process is supercritical and conditioned on surviving. Let for instance M_n be the location of the leftmost particle in the n th generation, that is, the smallest label among the labels of all nodes at depth n in the tree. Assume for simplicity that each individual has two children with i.i.d. displacements, say with distribution D . Then by construction, a typical line of descent (i.e., the labels on the successive nodes on an infinite path from the root) is equal in distribution to a random walk with step distribution D , thus drifting to $+\infty$ if $\mathbb{E}D > 0$. However, M_n is then equal in distribution to the minimum between 2^n random walks, and although a typical line of descent goes to $+\infty$, the exponential explosion in the number of particles makes it possible for the minimal displacement M_n to follow an atypical trajectory and, say, diverge to $-\infty$. Finer results are even available, and the speed at which M_n diverges has been initiated in a classical work by Hammersley [29] (who was interested in general branching processes), and later extended by Kingman [30] and Biggins [31] leading to what is now commonly referred to as the *Hammersley—Kingman—Biggins theorem*. For instance, in the simple case with binary offspring and i.i.d. displacements, it can be shown that $M_n \rightarrow -\infty$ if $\inf_{\theta \geq 0} \mathbb{E}(e^{-\theta D}) > 1/2$ and simple computations even give a precise idea of the speed at which this happens. Indeed, if $S_n^{(k)}$ for $k = 1, \dots, 2^n$ are the 2^n labels of the nodes at depth n in the tree, we have by definition for any $a \in \mathbb{R}$

$$\begin{aligned} \mathbb{P}(M_n \leq an) &= \mathbb{P}\left(S_n^{(k)} \leq an \text{ for some } k \leq 2^n\right) \\ &\leq \sum_{1 \leq k \leq 2^n} \mathbb{P}\left(S_n^{(k)} \leq an\right) \end{aligned}$$

using the union bound for the last inequality. As the $S_n^{(k)}$'s are identically distributed, say

with common distribution S_n equal to the value at time n of a random walk with step distribution D , we obtain for any $\theta \geq 0$

$$\begin{aligned} \mathbb{P}(M_n \leq an) &\leq 2^n \mathbb{P}(S_n \leq an) \\ &\leq 2^n \left[e^{\theta an} \mathbb{E}(e^{-\theta S_n}) \right] \leq [2\mu(a)]^n \end{aligned}$$

using Markov inequality for the second inequality, and defining $\mu(a)$ as $\mu(a) = \inf_{\theta \geq 0} (e^{\theta a} \mathbb{E}(e^{-\theta D}))$ in the last term. In particular, $\mathbb{P}(M_n/n \leq a) \rightarrow 0$ if a is such that $\mu(a) < 1/2$, which makes $M_n/n \rightarrow \gamma$, with $\gamma = \inf\{a : \mu(a) > 1/2\}$, the best we could hope for. It is quite surprising that these simple computations lead to the right answer, but the almost sure convergence $M_n/n \rightarrow \gamma$ is indeed the content of the aforementioned Hammersley—Kingman—Biggins theorem.

The case $\gamma = 0$ can be seen as a critical case, where the speed is sublinear; for a large class of branching random walks, this case also corresponds, after some renormalization (typically, centering the branching random walk), to study the second-order asymptotic behavior of M_n for a general γ . In the case $\gamma = 0$, several asymptotic behaviors are possible and the reader can for instance consult Addario-Berry and Reed [32] for more details. Bramson [33] proved that if every particle gives rise to exactly two particles and the displacement takes the value 0 or 1 with equal probability, then $M_n - \log \log n / \log 2$ converges almost surely. Recently, Aïdékon [34] proved in the so-called boundary case that $M_n - (3/2) \log n$ converges weakly.

These results concern the behavior of the extremal particle, and there has recently been an intense activity to describe the asymptotic behavior of all extremal particles, that is, the largest one, together with the second largest one, and third largest one. Informally, one is interested in the behavior of the branching random walk “seen from its tip,” which technically amounts to consider the point process recording the distances from every particle to the extremal one. This question was recently solved by Madaule [35], building on previous results by different authors, in particular the aforementioned work by Aïdékon [34]. The limiting point process can be seen as a “colored” Poisson process, informally obtained by attaching to each

atom of some Poisson process independent copies of some other point process.

Initially, one of the main motivations for studying the extremal particle of a branching random walk comes from a connection with the theory of partial differential equations. Namely, one can consider a variation of the branching random walk model, called the *branching Brownian motion*. In this model, time and space are continuous; each particle lives for a random duration, exponentially distributed, during which it performs a Brownian motion, and is replaced on death by k particles with probability p_k . Then, McKean [36] and later Bramson [37] observed that if $\sum_k k p_k = 2$ and $\sum_k k^2 p_k < +\infty$, then the function $u(t, x) = \mathbb{P}(M(t) > x)$, with $M(t)$ now the maximal displacement of the branching Brownian motion at time t , that is, the location of the rightmost particle, is a solution to the so-called Kolmogorov—Petrovskii—Piskunov (KPP) equation, which reads

$$\frac{\partial u}{\partial t} = \frac{1}{2} \frac{\partial^2 u}{\partial x^2} + \sum_{k \geq 1} p_k u^k - u$$

with the initial condition $u(0, x) = 1$ if $x \geq 0$ and $u(0, x) = 0$ if $x < 0$. One of the key properties of the KPP equation is that it admits traveling waves: there exists a unique solution satisfying

$$u(t, m(t) + x) \rightarrow w(x) \text{ uniformly in } x \text{ as } t \rightarrow +\infty.$$

Using the connection with the branching Brownian motion, Bramson [37] was able to derive extremely precise results on the position of the traveling wave, and essentially proved that $m(t) = \sqrt{2}t - (3/2^{3/2})\log t$. In probabilistic terms, this means that $M(t) - \sqrt{2}t + (3/2^{3/2})\log t$ converges weakly. Similarly as for the branching random walk, there has recently been an intense activity to describe the branching Brownian motion seen from its tip, which culminated in the recent works by Arguin *et al.* [38] and Aïdékon [34].

Beyond the behavior of extremal particles, the dependency of the branching random walk on the space dimension has been

investigated in Refs 39–45. There are also a number of articles for the so-called catalytic random walk when the particles performing random walk on $\mathbb{Z}^d$ reproduce at the origin only [42, 46, 47] for which a wide range of phenomena has been investigated. For this and more, the reader can for instance consult the recent survey by Bertacchi and Zuccha [48].

CONTINUOUS STATE BRANCHING PROCESSES

From a modeling standpoint, it is natural in the context of large populations to wonder about branching processes in continuous time and with a continuous state space. In the same vein, Brownian motion (or, more generally, a Lévy process) approximates a random walk evolving on a long time scale. The definition (1) does not easily lend itself to such a generalization.

An alternative and, from this perspective, more suitable characterization of Galton—Watson processes is through the branching property. If Z^y denotes a Galton—Watson process started with $y \in \mathbb{N}$ individuals, the family of processes $(Z^y, y \in \mathbb{N})$ is such that

$$Z^{y+z} \stackrel{(d)}{=} Z^y + \tilde{Z}^z, y, z \in \mathbb{N}, \quad (3)$$

where $\stackrel{(d)}{=}$ means equality in distribution and $\tilde{Z}^z$ is a copy of Z^z , independent from Z^y . In words, a Galton—Watson process with offspring distribution X started with $y + z$ individuals is stochastically equivalent to the sum of two independent Galton—Watson processes, both with offspring distribution X , and where one starts with y individuals and the other with z . It can actually be shown that this property uniquely characterizes Galton—Watson processes, and Lamperti [49] uses this characterization as the definition of a continuous state branching process (CSBP). Formally, CSBPs are the only time-homogeneous Markov processes (in particular, in continuous time) with state space $[0, \infty]$ that satisfy the branching property, see also Ikeda *et al.* [50] for more general state spaces. Note that even in the case of real-valued branching processes, the

state space includes $+\infty$: in contrast with Galton—Watson branching processes, CSBP can in principle explode in finite time.

One of the achievements of the theory is the complete classification of CSBPs, the main result being a one-to-one correspondence between CSBPs and Lévy processes with no negative jumps and, in full generality, possibly killed after an exponential time. This result has a long history dating back from Lamperti [49], for which the reader can find more details in the introduction of Caballero *et al.* [51] (note that CSBPs were first considered by Jiřina [52]). There are two classical ways to see this result. Until further notice, let $Z = (Z(t), t \geq 0)$ be a CSBP started at $Z(0) = 1$.

The first one is through random time-change manipulations, and more specifically through the Lamperti transformation $\mathcal{L}$ that acts on positive functions as follows. If $f : [0, \infty) \rightarrow [0, \infty)$, then $\mathcal{L}(f)$ is defined implicitly by $\mathcal{L}(f)(\int_0^t f) = f(t)$ for $t \geq 0$, and explicitly by $\mathcal{L}(f) = f \circ \kappa$ with $\kappa(t) = \inf\{u \geq 0 : \int_0^u f > t\}$. Then, it can be proved that $\mathcal{L}(Z)$ is a Lévy process with no negative jumps, stopped at 0 and possibly killed after an exponential time; conversely, if Y is such a Lévy process, then $\mathcal{L}^{-1}(Y)$ is (well defined and is) a CSBP.

The second way is more analytical. Let $u(t, \lambda) = -\log \mathbb{E}(e^{-\lambda Z(t)})$: then u satisfies the semigroup property $u(s + t, \lambda) = u(s, u(t, \lambda))$, which leads, for small $h > 0$, to the approximation

$$\begin{aligned} u(t + h, \lambda) - u(t, \lambda) &= u(h, u(t, \lambda)) - u(0, u(t, \lambda)) \\ &\approx h \frac{\partial u}{\partial t}(0, u(t, \lambda)) = -h \Psi(u(t, \lambda)) \end{aligned}$$

once one defines $\Psi(\lambda) = -\frac{\partial u}{\partial t}(0, \lambda)$. It can indeed be shown that u satisfies the so-called branching equation

$$\frac{\partial u}{\partial t} = -\Psi(u), \quad (4)$$

with boundary condition $u(0, \lambda) = \lambda$. In particular, Ψ uniquely characterizes u , and thus Z , and it is called the *branching mechanism* of Z . Moreover, it can be proved that Ψ is a Lévy exponent, that is, there exists a Lévy process Y with no negative jumps such

that $\Psi(\lambda) = -\log \mathbb{E}(e^{-\lambda Y(1)})$ or equivalently, in view of the Lévy—Khintchine formula, Ψ is of the form

$$\begin{aligned} \Psi(\lambda) &= \varepsilon + \alpha\lambda - \frac{1}{2}\beta\lambda^2 \\ &\quad + \int_{(0, \infty)} (1 - e^{-\lambda x} - \lambda x \mathbf{1}_{\{x < 1\}}) \pi(dx) \end{aligned}$$

for some measure π satisfying $\int_{(0, \infty)} (1 \wedge x^2) \pi(dx) < +\infty$ and some parameters $\varepsilon, \beta \geq 0$, and $\alpha \in \mathbb{R}$. Conversely, any Ψ of this form is the branching mechanism of a CSBP, and as Lévy processes are characterized by their Lévy exponent, this provides an alternative view on the one-to-one correspondence between CSBPs and Lévy processes.

The long-term behavior of CSBPs was one of the earliest questions studied by Grey [53], and they exhibit a richer range of behavior than Galton—Watson processes. First, Z is conservative, that is, $\mathbb{P}(Z(t) < +\infty) = 1$ for every $t \geq 0$, if and only if $1/\Psi$ is integrable at $0+$, a sufficient condition for this being that $\Psi(0) = 0$ and $\Psi'(0) > -\infty$. Further, we observe by differentiating the branching equation (4) with respect to λ and using $\mathbb{E}(Z(t)) = \frac{\partial u}{\partial \lambda}(t, 0)$ that $\mathbb{E}(Z(t)) = \exp(-\Psi'(0)t)$, which suggests to classify a (conservative) CSBP as subcritical, critical, or supercritical according to whether $\Psi'(0) > 0$, $\Psi'(0) = 0$, or $\Psi'(0) < 0$, respectively. This classification turns out to be essentially correct for conservative processes, under the additional requirement $\beta > 0$: in this case, supercritical processes may survive forever, with probability $e^{-\lambda_0}$ where λ_0 is the largest root of the equation $\Psi(\lambda) = 0$, while critical and subcritical processes die out almost surely, that is, the time $\inf\{t \geq 0 : Z(t) = 0\}$ is almost surely finite.

When $\beta = 0$, the situation may be slightly different. indeed, for any CSBP, the extinction probability $\mathbb{P}(\exists t \geq 0 : Z(t) = 0)$ is strictly positive if and only if $1/\Psi$ is integrable at $+\infty$ and $\Psi(\lambda) > 0$ for λ large enough; in this case, the extinction probability is equal to $e^{-\lambda_0}$ with λ_0 as discussed earlier. In particular, we may have a subcritical CSBP (with $\Psi'(0) > 0$) satisfying both $\beta = 0$ and $\int^\infty (1/\Psi) = +\infty$, in which case $Z(t) \rightarrow 0$ but $Z(t) > 0$ for every $t \geq 0$. In other words, although Z vanishes,

in the absence of the stochastic fluctuations induced by β , it never hits 0. This behavior is to some extent quite natural, because the α term corresponds to a deterministic exponential decay (for $\Psi(\lambda) = \alpha\lambda$ we have $Z(t) = e^{-\alpha t}$) and the jumps of Z are only positive, so one needs stochastic fluctuations in order to make Z hit 0.

We have mentioned in the beginning of this section the motivation for studying CSBPs as continuous approximations of Galton—Watson processes. This line of thought is actually present in one of the earliest articles by Lamperti [54] on the subject. In particular, CSBPs are the only possible scaling limits of Galton—Watson processes, that is, if $(Z^{(n)}, n \geq 1)$ is a sequence of Galton—Watson processes with $Z_0^{(n)} = n$ such that the sequence of rescaled processes $(\bar{Z}^{(n)}, n \geq 1)$, where $\bar{Z}^{(n)}(t) = Z_{[ant]}^{(n)}/n$ for some normalizing sequence a_n , converges weakly to some limiting process $\bar{Z}$, then $\bar{Z}$ must be a CSBP. And conversely, any CSBP can be realized in this way.

There is, at least informally, an easy way to see this result, by extending the Lamperti transformation at the discrete level of Galton—Watson processes. Indeed, consider $(S(k), k \geq 0)$ a random walk with step distribution $X' = X - 1$ for some integer-valued random variable X , and define recursively $Z_0 = S(0)$ and $Z_{n+1} = S(0) + S(Z_1 + \dots + Z_n)$ for $n \geq 0$. Then, writing $S(k) = S(0) + X'_1 + \dots + X'_k$ with (X'_k) i.i.d. copies of X' , we have

$$\begin{aligned} Z_{n+1} - Z_n &= X'_{Z_1 + \dots + Z_{n-1} + 1} \\ &\quad + \dots + X'_{Z_1 + \dots + Z_{n-1} + Z_n} \end{aligned}$$

and so Z_{n+1} is the sum of Z_n i.i.d. copies of $X' + 1$, that is, Z_n is a branching process with offspring distribution X . This realizes Z as the time-change of a random walk, and leveraging on classical results on the convergence of random walks toward Lévy processes and continuity properties of the time-change involved [55], one can prove that the limit of any sequence of suitably renormalized Galton—Watson processes must be the time-change of a Lévy process, that is, a CSBP. This approach is for instance carried on by Ethier and Kurtz [56].

If a CSBP can be viewed as a continuous approximation of a Galton—Watson process, it is natural to ask about the existence of a corresponding genealogical structure. This question was answered by Duquesne and Le Gall [57], who for each CSBP Z exhibited a process H , which they call height process, such that Z is the local time process of H . This question is intrinsically linked to the study of continuum random trees initiated by Aldous [58,59]. As a side remark, note that this genealogical construction plays a key role in the construction of the Brownian snake [60]. There has also been considerable interest in CSBP allowing immigration of new individuals: these processes were defined by Kawazu and Watanabe [61], their genealogy studied by Lambert [62] and the corresponding continuum random trees by Duquesne [63].

Finally, let us conclude this section on CSBPs by mentioning superprocesses. Superprocesses are the continuous approximations of branching random walks, in the same vein as CSBPs are continuous approximations of Galton—Watson processes. They were constructed by Watanabe [64], and can technically be described as measure-valued Markov processes. Similarly as for the branching Brownian motion, Dynkin [65] showed that superprocesses are deeply connected to partial differential equations. The recent book by Li [66] offers a nice account on this topic.

AGE REPLACEMENT POLICIES

Division of Statistics, Northern
Illinois University, DeKalb,
Illinois

INTRODUCTION

Maintenance-management activities have become part of the overall quality improvement in many companies. Preventive maintenance is a schedule of planned maintenance activities aimed at the prevention of breakdown and failures. The primary goal of preventive maintenance is to prevent the failure of a unit before it actually occurs. We assume an understanding of a unit which when placed in a socket performs some operational function, see Ascher and Feingold [1] for more details. Most preventive maintenance strategies are based on the use of planned replacements made before the failure and service rectification made after failure. Planned replacements are generally less expensive than service replacements. For different planned replacement policies we refer you to Barlow and Proschan [2], Sahin and Polatoglu [3], Yeh *et al.* [4], Chien [5], and many references cited there.

One of the basic and simple replacement policies is the age replacement (AR) policy. Under an AR policy we replace a unit at failure or at the end of a specified time interval, whichever occurs first. Of course, this makes sense if a failure replacement costs more than a planned replacement. If a unit is replaced upon its failure only, then we refer to this policy as a renewal replacement (RR) policy.

Sometimes, in practice, the age of a unit is measured in more than one timescale, for example, cars age in the “parallel” scales of calendar time since purchase and the number of miles driven. In such situations, a maintenance policy should take into account the parallel scales in which a unit operates. AR

policies can also be developed based on several timescales. For more details see Frickenstein and Whitaker [6] and many references cited there. In this article, however, we concentrate on the AR policy based on a single timescale.

The article is organized as follows. In the section titled “Properties of Age Replacement Policy”, we give several properties of AR policy. In the section titled “Optimal Age Replacement Policy”, we obtain an optimal AR policy. Finally, in the section titled “Multivariate Age Replacement”, we define a multivariate version of AR policy and give its properties.

PROPERTIES OF AGE REPLACEMENT POLICY

Let X be a nonnegative continuous random variable representing the time to failure of a unit. Let $\bar{F}(x) = P(X > x)$ be the survival function of X and $F(x) = 1 - \bar{F}(x)$ be the cumulative distribution function of X . The probability density and the hazard functions of X are $f(x) = -\frac{d}{dx}(\bar{F}(x))$ and $h(x) = \frac{f(x)}{\bar{F}(x)}$, respectively. It is assumed that there are many identical items in stock for this unit.

Let $N(t)$ be the number of failures in $[0, t]$ for an RR policy and $N_{AR}(t, T)$ be the number of failures in $[0, t]$ under an AR policy with replacement interval T . Suppose W_i and $W_i(AR)$ are the intervals between $(i - 1)$ th and i -failure under RR and AR with replacement interval T policies respectively, $i = 1, 2, \dots$. Then,

$$P(W_i > x) = \bar{F}(x), i = 1, 2, \dots,$$

and

$$P(W_i(AR) \geq x) = ((\bar{F}(T))^j \bar{F}(x - jT))$$

$$\text{for } jT \leq x \leq (j + 1)T,$$

$$j = 0, 1, 2, \dots, i = 1, 2, \dots$$

Using the above equations the following result holds.

Result 1. For all $t \geq 0, T \geq 0, P(N(t) \geq k) \geq P(N_{AR}(t, T) \geq k)$ for $k = 0, 1, 2, \dots$ if and only if $\bar{F}$ is new better than used (NBU). $\bar{F}$ is said to be NBU if $\bar{F}(x+y) \leq \bar{F}(x)\bar{F}(y)$ for all $x, y \geq 0$.

The above result states that NBU class of life distributions is the largest class for which AR diminishes stochastically the number of failures experienced in any particular time interval $[0, t], 0 < t < \infty$. In this sense, the class of NBU distributions is a natural class to consider in studying AR. As an application of the above result consider the Weibull distribution $\bar{F}(x) = \exp(-\alpha x^\beta), x > 0, \beta \geq 1, \alpha > 0$. For this distribution, since $\bar{F}$ is NBU, one can conclude that in any interval the chance of having a smaller number of failures under AR policy is higher compared to RR policy.

It is not always possible to carry out preventive replacement at any moment in time. In an opportunity-based age replacement (OAR) preventive replacements are possible at randomly occurring opportunities. Therefore, in the OAR strategy, replacement of a unit occurs at the first opportunity after a specified age, say T . See Coolen-Schrijner *et al.* [7] and many references cited there.

If $W_i(\text{OAR})$ be the interval between the $(i-1)$ st and i th failure under OAR, $i = 1, 2, \dots$, then,

$$\begin{aligned} P(W_i(\text{OAR}) \geq x) &= \int \cdots \int \bar{F}(T+y_1)\bar{F}(T+(y_2-y_1)) \cdots \\ &\quad \bar{F}(T+(y_j-y_{j-1}))\bar{F}(x-(jT+y_j)) \quad (1) \\ &\quad \times \prod_{l=1}^j f(y_l) dy_1 dy_2 \cdots dy_j, \\ &\quad j = 1, 2, \dots, i = 1, 2, \dots, \end{aligned}$$

where the integral is over the set $A = \{(y_1, \dots, y_j) : 0 \leq y_l \leq T \text{ and } jT + y_j < x < (j+1)T\}$.

Using Equation (1), we get the following result.

Result 2. For all $t \geq 0, T \geq 0, P(N(t) \geq k) \geq P(N_{OAR}(t, T) \geq k), k = 0, 1, 2, \dots$ if and only if $\bar{F}$ is NBU. Here, $N_{OAR}(t, T)$ is the number of failures in $[0, t]$ under the OAR strategy with replacement interval T .

The above result is very interesting in the sense that under OAR, which is administratively easier to implement than AR, the NBU class of life distributions is still the largest class where the chance of having a smaller number of failures under OAR policy is higher compared to RR policy. Also, like AR policy, the class of NBU distributions is a natural class to consider in studying OAR.

OPTIMAL AGE REPLACEMENT POLICY

An AR cycle starts immediately after the installation of a new unit, with survival function $\bar{F}$, and ends with its failure, or after an operating time T , whichever comes first. If a cycle ends with a failure at age $x \leq T$, an unplanned failure replacement is performed, the cost $c_s + c_q = c_f$ is incurred and a new cycle starts. Here c_s represents the service replacement cost, c_q the failure cost and c_f is the total cost. If the unit does not fail before time T , then the preventive maintenance is carried out, the planned replacement cost, c_p , is incurred and a new cycle starts. It should be noted that the assumption of independent identically distributed (i.i.d.) failure times implies i.i.d. cycles. Throughout this section, we assume that $c_f \geq c_p$ which makes sense in many practical applications.

The average length of an AR cycle is $\int_0^T \bar{F}(x) dx$. Also, the average planned replacement, service replacement, and failure costs during the cycle are $c_p \bar{F}(T), c_s \bar{F}(T)$, and $c_q \bar{F}(T)$ respectively. Now, letting $C(T)$ denote the long-run average cost (cost rate) of an AR strategy for the unit, we then have

$$\begin{aligned} C(T) &= \frac{E(C_0(T))}{E(T_0(T))} \\ &= \frac{c_p \bar{F}(T) + c_f \bar{F}(T)}{\int_0^T x f(x) dx + \int_0^T T f(x) dx} \\ &= \frac{c_p \bar{F}(T) + c_f \bar{F}(T)}{\int_0^T \bar{F}(x) dx}, \quad (2) \end{aligned}$$

where $T_0(T) = \begin{cases} x, & \text{if } x \leq T \\ T, & \text{if } x > T \end{cases}$ and $C_0(T) = \begin{cases} c_f, & \text{if } x \leq T \\ c_p, & \text{if } x > T \end{cases}$ are cycle time and cycle

cost for replacement age T . In Equation (2), if we let $T \rightarrow 0$, then $C(T) \rightarrow \infty$. Also, if $T \rightarrow \infty$ (service replacement only policy), then $C(T) = \frac{c_f}{\mu}$, where $\mu = E(X)$ is the expected lifetime of the unit. That is, an AR policy $T(T < \infty)$ is justified if $C(T) \leq \frac{c_f}{\mu}$.

Using Equation (2), the optimal rectification period, T^* , can be obtained by minimizing the $C(T)$. More specifically,

$$C'(T) = \frac{\bar{F}(T)}{\left(\int_0^T \bar{F}(x) dx\right)^2} [(c_f - c_p)L(T) - c_f], \quad (3)$$

where $L(u) = h(u) \int_0^u \bar{F}(x) dx + \bar{F}(u)$. Now $L'(u) = h'(u) \int_0^u \bar{F}(x) dx$ and therefore if $h(t)$ is nondecreasing (nonincreasing), then $L(u)$ is nondecreasing (nonincreasing). Thus, if X has a nonincreasing failure rate (DFR) distribution, then $T^* = \infty$. If X has a nondecreasing failure rate (IFR) distribution, then T^* can be obtained by solving the following equation

$$L(T^*) = \frac{c_f}{c_f - c_p}, \quad (4)$$

provided that $\mu h(\infty) \geq \frac{c_f}{c_f - c_p}$. This means if $h(\infty) \cdot \mu < \frac{c_f}{c_f - c_p}$, then $T^* = \infty$.

As an application, consider the following example.

Example 1. Let X be the lifetime of a unit. The failure distribution of X is described by a 2-parameter Weibull distribution, with $\beta = 2.5$ and $\alpha = 1000$ h. That is, $\bar{F}(x) = \exp(-1000x^{2.5})$. Suppose the cost of corrective maintenance is $c_f = \$5$ and the cost for a preventive replacement is $c_p = \$1$. Solving Equation (4), $T^* \approx 493.047$. That is, the optimum replacement age is about 493.047 h.

Suppose the hazard function of X , $h(x)$ contains IFR regions. Examples of such hazard functions include bathtub hazard function and inverse bathtub hazard function. For such hazard functions $L(u)$ has local maximum at the end of each IFR region, and the global maximum value will exist at the end of one of the IFR regions. Also, one can obtain

T^* by still solving Equation (4) provided that $h(t_m)\mu > \frac{c_f}{c_f - c_p}$, where t_m corresponds to maximum $h(t)$. For more details see, Amari and Fulton [8] and references cited there.

Under OAR, the random length $T_{\text{OAR}}(T)$ and cost $L_{\text{OAR}}(T)$ of the cycle under consideration are

$$T_{\text{OAR}}(T) = \min(X, T + Y), \quad (5)$$

and

$$L_{\text{OAR}}(T) = c_p I(X \geq T + Y) + c_f I(X < T + Y), \quad (6)$$

where Y is the residual time to the next opportunity. Using Equations (5) and (6), the expected cost function is

$$\begin{aligned} C_{\text{OAR}}(T) &= E\left(\frac{L_{\text{OAR}}(T)}{T_{\text{OAR}}(T)}\right) \\ &= \frac{c_f}{E(X)} P(X < T + Y) \\ &\quad + \frac{c_p}{T + E(Y)} P(X \geq T + Y). \end{aligned} \quad (7)$$

Under a one-cycle criterion, the optimal threshold age T_{OAR}^* can be obtained by minimizing $C_{\text{OAR}}(T)$ in Equation (6). For more details, we refer you to Coolen-Schrijner *et al.* [7].

As an application consider the following example.

Example 2. Continuing from Example 1, keeping $c_p = 1, c_f = 5$, and $\bar{F}(x) = \exp(-1000x^{2.5}), x \geq 0$. Assume Y has the uniform distribution over the interval $(0-20)$. Solving Equation (7), $T_{\text{OAR}}^* \approx 505.28$. That is, under OAR policy, the optimum replacement age is about 505.28 h.

MULTIVARIATE AGE REPLACEMENT

Frequently, in reliability theory, we deal with a system that consists of two or more sockets and their associated units or components, interconnected to perform one or more functions. Consider a system with k components. In this section, we describe the following two replacement policies, which are extensions of

AR and RR to the multivariate case. For more details see Ebrahimi [9].

1. Under a multivariate age replacement (MAR) policy, component i of a system is replaced either at age T_i , or upon its failure, $i = 1, \dots, k$. We refer to this as the MAR at $(T_1, T_2, \dots, T_k)$.
2. Under a multivariate renewal replacement (MRR), components are replaced upon their failures.

For simplicity we confine our study to the case where $k = 2$ and define the following counting processes:

- $N_i(t)$ = the number of component i failures in $(0, t]$ under MRR, $i = 1, 2$;
- $N_{AR}(t; i, T)$ = the number of component i failures in $(0, t]$ under MAR (T, T) , $i = 1, 2$.

Let X_1 and X_2 be two nonnegative continuous random variables representing the times to failure of components 1 and 2, respectively. Let $\bar{F}(x_1, x_2) = P(X_1 > x_1, X_2 > x_2)$ be the joint survival function of X_1 and X_2 and $\bar{F}_{X_i}(x_i) = P(X_i > x_i)$ be the survival function of X_i , $i = 1, 2$. It is assumed that $\bar{F}(0, 0) = \bar{F}_{X_1}(0) = \bar{F}_{X_2}(0) = 1$ and $\bar{F}(\infty, \infty) = \bar{F}_{X_1}(\infty) = \bar{F}_{X_2}(\infty) = 0$. We denote the conditional survival function of X_1 given $X_2 > y$ and the conditional survival function of X_2 given $X_1 > x$ by

$$\bar{H}_y^{(1)}(x) = P(X_1 > x | X_2 > y), \quad (8)$$

and

$$\bar{H}_x^{(2)}(y) = P(X_2 > y | X_1 > x), \quad (9)$$

respectively.

Before we present our main result in this section, we need to make the following assumptions.

1. As soon as a component of the system fails or it reaches the age T , it will be replaced by a new and an identical component whose lifetime is independent of the replaced component but is dependent on the lifetimes of the components that are currently in service.

2. The replacement time (the time it takes to replace either component) is negligible.

The following result which is an extension of Result 1 to the bivariate case provides a stochastic comparison of failures experienced under MAR (T, T) and MRR.

Result 3. If (a) $\bar{F}(x + t_1, x + t_2) \leq \bar{F}(x, x)$ for all $x, t_1, t_2 \geq 0$ and (b) $\bar{H}_x^{(i)}(t_1 + t_2) \leq (\geq) \bar{H}_x^{(i)}(t_1) \bar{H}_x^{(i)}(t_2)$, $i = 1, 2$, for all $x, t_1, t_2 \geq 0$, then

$$\begin{aligned} P(N_1(t_1) \leq n_1, N_2(t_2) \leq n_2) & (\leq) \\ & \geq P(N_{AR}(t_1; 1, T) \leq n_1, N_{AR}(t_2; 2, T) \leq n_2) \end{aligned} \quad (10)$$

for all $n_1, n_2, t_1, t_2 \geq 0$.

The above result says that under conditions (a) and (b), MAR (T, T) diminishes stochastically the number of failures experienced in any particular time intervals $[0, t_1]$ and $[0, t_2]$, $0 < t_1, t_2 < \infty$ by components 1 and 2 respectively. As an application, suppose the joint failure distribution of components 1 and 2 is described by a bivariate Gumbel distribution,

$$\begin{aligned} \bar{F}(x, y) &= \exp(-\lambda_1 x - \lambda_2 y - \lambda_3 xy), \quad x, y > 0, \\ \lambda_1, \lambda_2, \lambda_3 &> 0. \end{aligned}$$

Since the assumptions of Result 3 holds for this distribution, we can claim that the chance of having less numbers of components 1 and 2 failures under MAR (T, T) policy is higher compared to MRR policy.

Optimal Replacement Policy under MAR (T, T)

In this section, we determine an optimal replacement policy T^* under MAR (T, T) such that

$$\begin{aligned} C(T, T) &= \frac{\text{the expected cost incurred in a cycle}}{\text{the expected length of a cycle}} \end{aligned} \quad (11)$$

is minimized. Here a cycle is the time between two consecutive system failures. We note that $C(T, T)$ is being used as the criterion for evaluating the replacement policies.

To evaluate $C(T, T)$ in Equation (11) we have to describe system failure. For that we need to know how the components are connected. In this section we consider the following cases.

Case I. The system works if both components work. Let c_f be the constant cost of replacement of one or both components at the system's failure and let c_p be the constant cost of a preventive replacement of both components at age T with $0 < c_p < c_f < \infty$. Since the system fails if at least one component fails, therefore the lifetime of the system in a given cycle, say j , is $\min(Y_1(j), Y_2(j))$ and the number of preventive replacements of both components at age T in the cycle is $[\min(Y_1(j), Y_2(j))/T]$. Here $Y_i(j)$ is the interval between $(j-1)$ th and j th arrivals of the process $N_A(t; i, T)$, $i = 1, 2$, $j = 1, 2, \dots$. Consequently, the total cost is

$$c_p[\min(Y_1(j), Y_2(j))/T] + c_f, \quad j = 1, 2, \dots, \quad (12)$$

where $[a]$ is the largest integer less than or equal to a . Now,

$$E(\min(Y_1(j), Y_2(j))) = \frac{1}{1 - \bar{F}(T, T)} \int_0^T \bar{F}(u, u) du, \quad j = 1, 2, \dots, \quad (13)$$

and

$$E\left[\frac{\min(Y_1(j), Y_2(j))}{T}\right] = \frac{\bar{F}(T, T)}{1 - \bar{F}(T, T)}. \quad (14)$$

Using Equations (14) and (15), Equation (12) reduces to

$$C_1(T, T) = \frac{1}{\int_0^T \bar{F}(u, u) du} (c_p \bar{F}(T, T) + c_f(1 - \bar{F}(T, T)))$$

$$= \frac{1}{\int_0^T \bar{F}(u, u) du} (c_f - \beta \bar{F}(T, T)), \quad (15)$$

where $\beta = (c_f - c_p) > 0$. We can determine the optimal replacement policy T^* by minimizing $C_1(T, T)$. The minimization procedure can be done by analytical or numerical methods. See Ebrahimi [9] for more details.

As an application consider the following example.

Example 3. Let X_1 and X_2 be lifetimes of components 1 and 2 respectively. The joint distribution of X_1 and X_2 is described by a 3-parameter bivariate Gumble distribution, with $\lambda_1 = \lambda_2 = \lambda_3 = 1$ year. That is, $\bar{F}(x, y) = \exp(-x - y - xy)$. Suppose the cost of corrective maintenance is $c_f = \$2$ and the cost for a preventative replacement is $c_p = \$1$. For this case, Equation (15) can be written as

$$\exp[-2T - T^2] + (2 + 2T) \int_0^T \exp[-2u - u^2] du = 2. \quad (16)$$

Solving Equation (16) we get T^* approximately equal to 0.27. That is, the optimum replacement age is about 3.12 months.

Case II. The system works if at least one component works. Under this case the system fails if both components fail, therefore the lifetime of the system in a given cycle, say j is $\max(Y_1(j), Y_2(j))$. Using arguments similar to those in Case I, Equation (9) reduces to

$$C_2(T, T) = \frac{c_p E[\max(Y_1(j), Y_2(j))/T] + c_f}{E(\max(Y_1(j), Y_2(j)))} = \frac{1}{\sum_{i=1}^2 \frac{\int_0^T \bar{F}_i(u) du}{1 - \bar{F}_i(T)} - \frac{\int_0^T \bar{F}(u, u) du}{1 - \bar{F}(T, T)}}$$

$$\times \left(c_f + c_p \sum_{i=1}^2 \frac{\bar{F}_i(T)}{1 - \bar{F}_i(T)} - \frac{c_p \bar{F}(T, T)}{x1 - \bar{F}(T, T)} \right). \quad (17)$$

We may proceed as in Case I and determine the optimal replacement policy T^* by minimizing $C_2(T, T)$ in Equation (17). However, unlike Case I, it is hard to obtain a general necessary condition for a unique and finite T^* (T^* is the time that minimizes Equation 17). Each parametric family of distributions must be studied separately in order to obtain such a condition.

AGGREGATE PLANNING

MIKE SWIHART

ArrowStream in Logistics
Engineering, Chicago,
Illinois

Aggregate planning creates a high level plan that has been simplified by combining a number of entities into a single entity. This article focuses on the application of aggregate planning to strategic situations for supply chains. A full supply chain starts with raw materials and ends with a final customer who uses finished goods. As such it can include facilities that supply raw materials, manufacture finished goods, and store products. It also includes the transportation links that connect these facilities. A supply chain will typically include multiple companies, since a single company normally does not encompass all of these functions [1]. Since the breadth and depth of a supply chain can be overwhelming, it is a good candidate for aggregate planning.

In strategic situations aggregate planning is used for developing models that inform strategic decisions. Some examples of these types of decisions include adding, removing, or changing suppliers, manufacturers, or storage locations. Other examples are changing the capabilities of a facility, or changing the transportation links between facilities. The reason why aggregate planning is used is because all the details are not required for the solution or where details cannot be included either because the construction would be too complex, the solve time would be too long, or a final solution would not be useful at that level of detail [2].

- *Strategic Applications of an Aggregate Plan.* In strategy the objective is to make decisions that are difficult to reverse, are expensive, and/or have an impact on a large number of other decisions. For example, in the context of optimizing a supply chain an aggregate

plan might combine a large number of UPCs. (A UPC is the Universal Product Code that identifies what a product is and who made it. UPCs are used on virtually all retail products. [1]) The aggregate planning model would be used for making decisions such as where to place a new production plant or where to add a new production line. For strategic situations, the typical implementation is to construct a number of aggregate plans, each one representing a scenario. After a set of scenarios has been made and optimized they are compared and analyzed. This is used to inform decisions.

- *Mathematical Approach for Aggregate Planning.* The mathematical approach behind aggregate planning is typically a linear program or LP (see the section titled “Linear Programming” in this encyclopedia). Sometimes some binary variables are required turning the problem into a mixed-integer program or MIP (see the section titled “Models and Algorithms” in this encyclopedia), but the majority of the structure will still be linear. The mathematical approaches for this type of problem are well developed, and software is employed that addresses the basic mathematical needs.
- *Types of Software Available for Aggregate Planning.* It is not uncommon to find software that is stand alone, and it is often PC based. While it is possible to solve aggregate planning models with a general LP solver, most often specialized software is used especially in the context of supply chain models. This is because this type of problem is well known and commonly desired structures and rules relating to facilities, production, shipping, inventory, and so on, can be anticipated, so it is worthwhile to have features built in to allow quick modeling.

- *Key Areas that are Challenges in Aggregate Planning.* There are several areas where issues can arise. One area is with respect to the mathematics itself. Other areas are more likely to be the source of challenges, including the business processes, the data processes, and the decision processes.

THE USE OF AGGREGATE PLANNING IN STRATEGY

What Is Strategic Aggregate Planning

Strategy addresses questions that can be characterized as being long term, being difficult to reverse, costing capital, having a significant expense, and/or affecting many other decisions. Further, to justify doing a true aggregate model there has to be a significant amount of complexity. If not, then aggregate plan can simply be a spreadsheet exercise. Some ways that it might be complicated could be a supply chain with a large number of products, a large number of production sites, or having many production lines capable of running different types of products with interactions between lines. There can also be complexity within the demand profile, such as a high seasonality. Another example is a situation where there are a significant number of vendors that give rebates when order quantities hit negotiated thresholds minimums.

When to Use Strategic Aggregate Planning

A model is most valuable when the system is in a significant state of change. New situations require new solutions. If the real-world situation is not changing very quickly, then the current supply chain setup can simply be maintained. If there is a reason to believe that the existing supply chain is suboptimal, then modeling can still be useful even if the current system is not changing. Obviously, it is preferred to optimize a supply chain immediately after a significant change rather than run suboptimally for some period of time.

One type of change is when there is a high level of growth in product demand,

either organic growth or growth thru acquisitions. There could be a large flux in the mix of products that are offered, or (hopefully not) a significant decrease in demand where the size of the supply chain needs to be reduced.

What Strategic Aggregate Planning Is NOT

Some of the things that aggregate planning is NOT intended to address are detailed production plans and it is definitely not intended to produce a production schedule. It follows that modeling at a UPC level is not appropriate. Production decisions on a short term basis are not an appropriate application. Low level decisions are not appropriate, such as trying to site a facility within a predefined metro area.

Aggregate planning is also not designed for optimizing inventory levels under uncertainty (see the section titled “Inventory Management and Control” in this encyclopedia). The most typical inventory question—“How much inventory should be carried to protect against probabilistic fluctuations in demand or supply?” is stochastic based. Aggregate planning is intended for problems that can be addressed with deterministic mathematical models. If the stochastic elements outweigh the deterministic parts of the problem then the problem is not well suited for aggregate planning. Of course it is true that with the use of many scenarios a variety of inputs values can be addressed, but aggregate planning does not take variability into account in the model itself (see the section titled “Stochastic Models” in this encyclopedia).

Questions Answered by a Strategic Aggregate Planning Model

There are a number of common strategic questions that aggregate planning is used to address in the context of a supply chain. First, it is used to determine when more production capacity is required. The capacity can be over all, by product, by region, or by time period. If the demand has been split into different sales channels then this can also be by channel. When more capacity is needed, a number of scenarios can be done

to investigate options for new plants, new individual production lines, and enhancements of existing production lines by adding capacity or new capabilities. These scenarios delve into the many options for the location, capability, and capacity for these capacity changes. Similarly, when there are large reductions in demand these analyses can be repeated but for a shrinking supply chain.

Another common set of questions center around the use of distribution centers (DCs). Aggregate planning is used to determine when a change in DC space is required, including options for expanding or contracting existing DCs, adding DCs, and closing DCs. Aggregate planning can help in determining which products to flow through which DCs, and to set service territories for DCs.

What Is Aggregated

At an appropriate level of detail this type of problem can have a very broad scope, and in fact the breadth of scope is often a driver requiring the detail to be aggregated. The scope can accommodate production, logistics, and inventory, with the key being how each of these is aggregated. All three of these are affected in the way that demand is aggregated. The demand will not be at a UPC level but instead at a product level. Demand would typically be at a monthly or even annual level as opposed to by shift or by day, and often not even by week. This means that production, logistics, and inventory will be aggregated at a product level for the same time buckets. The demand may not be at the customer level since a company can have thousands of ship to points for customers. Instead the demand may be by metro area or even by DC, the warehouse that faces the customer, which determines how the logistics flow will be aggregated. This implies that individual loads are aggregated, so that the aggregate plan only has overall product flow. Further, facilities are often included for storing inventory, but some may be aggregated. If there are several outside warehouses in one metro area, they may be modeled as one large storage space. While these are common types of aggregation, other

entities may require aggregation depending on the details of the system.

What Is Included in a Strategic Aggregate Planning Model

Production. Production is commonly included. Production can be by line and by product. It can take into account external and internal production along with the differences in variable production costs by site, for example, labor, materials, ingredients, and utilities. Tiered pricing and rebates can also be included for external production sources. Production can take into account the capacity limits and can take into account the labor constraints at an aggregate level. Even though there is some level of aggregation in the products themselves, individual product lines typically do not need to be aggregated. Despite the fact that a broad scope of production information is included in a strategic aggregate plan, the output is not intended to be a production schedule.

Logistics. Logistics is normally included, with interfacility transportation, customer shipping, and shuttles. The cost of lane rates, fuel, and handling can be included. Multiple modes can be included, such as over the road truck versus rail but this is an aspect that may also require aggregation. However the aggregation requires that individual loads are not considered. What is considered is the flow between facilities or from a facility to a customer.

Inventory. Finally it is not uncommon to include inventory with safety stock and pre-building limits. Costs can be included for storage costs, cost of capital, and related items. The inventory would be constrained between a preset minimum and maximum. These limits are inputs to the plan, and are not being calculated by it to take into account the variability of demand or supply (see the section titled "Inventory Management and Control" in this encyclopedia). Other forms of modeling would be used to set the appropriate level of inventory based on a target level of product availability or stock out.

MATHEMATICAL ISSUES

What Are the Mathematics

The fundamental mathematical approach behind aggregate planning is an LP (see the section titled “Linear Programming” in this encyclopedia) or a mixed integer program (see the section titled “Models and Algorithms” in this encyclopedia). The vast majority of the structure is linear. The reasons why binary variables are introduced are due to cost structure or the need to capture particular system behavior. An example of a cost structure that requires binary variables is a third party supplier that has tiered pricing or provides a rebate for production above a certain threshold. An example of a system behavior that requires binary variables is when there is plant or third party supplier that is only operationally viable when a minimum amount of production is reached. In that case the model has the choice between no production at that site or production at least equal to the minimum.

Strategic models also use binary variables as an efficient means to sort through many options. For example, a manufacturer might need to add the capability to produce a new product, and have to choose from 20 existing manufacturing lines located in six existing plants, with a capital cost for each line where the capability is added. Rather than run a separate model for each option, a single model that is permitted to choose between the options is sometimes more efficient. This introduces binary variables. This approach has the drawback that the results given only cover the optimal solution. Very little information is gained on good solutions that are suboptimal, that is, the runner-up solutions, so this approach is not as useful as it first appears.

What Are the Challenges in the Mathematics

Usually the mathematics are taken care of in the software. The areas where the math becomes important are in developing the structure and determining how to approach the scenarios. Constructing the model itself requires some knowledge of the impact of adding linear variables and binary variables,

especially around the impact on the combinatorics. This is important because of the impact on the time to solve or optimize a scenario. In a business context, a good solution in a reasonable amount of time is more valuable than a perfect solution that comes too late. Some knowledge of the mathematics is needed to know when to make trade-offs between the accuracy of having a set of binary variables to get the right behavior or cost structure versus using an approximation to reduce the solve time.

Some amount of mathematical knowledge is also useful because most programs will allow some level of control within the LP, or branch and bound for MIPs. Knowledge of the mathematics that is used in these approaches can be useful in knowing what settings can be helpful when a scenario is taking too long to optimize. It is also good to have some knowledge of the combinatorics so that when there are equally valid choices in structure, the one that minimizes the time to optimize can be chosen.

Further, when using the output of a strategy aggregate model financial concepts such as the time value of money, internal rate of return (IRR), and net present value (NPV) will all come into play in the final decision. These may or may not be incorporated into the model itself. The proper mathematical background is helpful to know how to use the output of a model that may span a single year for a decision that affects many years.

What Can be done about the Challenges in the Mathematics

As far as the mathematical approach is concerned, the basic math is largely well solved. When and if the time to optimize is inordinately long the business is typically sufficiently well understood to know what trade-offs in model construction are reasonable to make. In other words, when the modeling is being done well, the modeler will know whether or not different elements of the cost or structure are critical and likely to drive the results. A good modeler will know where large amounts of detail are required and what areas can be approximated. The implication of this is that to address the mathematical challenges that may arise

what is normally required is not just an understanding of the mathematics but also a strong understanding of the business.

BUSINESS PROCESS

What Is the Business Process

Strategic aggregate planning is project oriented and not a continuous process like normal operational production planning. There is a specific set of questions that are to be answered in a reasonable amount of time to make a long-term decision in a timely manner. The business process tends to be more difficult than the mathematics. For example, if a supply chain requires an additional capacity, then the decision to be made using aggregate planning may be to determine a good location for a new plant that will be cost effective for many years. However, the decisions need to be made such that the plant can be built soon enough to avoid cutting sales or at least to avoid expensive manufacturing alternatives for an extended period.

This means that the project output required is not just a single optimal answer but a complete analysis to inform the decision. In most studies this requires not just the optimal result but also a number of good, suboptimal alternatives, with enough detail for financial analysis. Internal customers or external customers who are going to use the information to make decisions need to see and understand the alternatives and see how close they are to the optimal solution. They need to weigh the calculated financial impact of choosing one option over another versus the difficulty in measuring intangible differences between scenarios. Further, a number of sensitivities are required to understand under what conditions a solution is good or even optimal and when it becomes a poor solution. Almost always scenarios will be needed that consider higher or lower sales, higher or lower costs for production or transportation, as well as scenarios that take into account other potential decisions that are in process in the organization.

A model can choose a solution that is operationally very different for a very small

amount of money from a small change in assumption values. This can lead to a solution that is unstable or brittle from an operational perspective. Since strategic decisions cannot be quickly changed, there is a benefit in choosing a suboptimal solution that is robust. For these reasons many explicit scenarios will be run. For reference, the author has seen many projects that required over 100 scenarios and a number of projects that used 500 scenarios. An individual modeler may do 750–1000 scenarios in a given year over several projects.

What Is the Workflow

The ideal work flow for an aggregate planning process would be as shown in Fig. 1. Note that it is expected even in the ideal case to be an iterative process where one result leads to more probing questions that require more scenarios. This is good thing because modeling should lead to a greater depth of understanding with new insights triggering more questions.

The actual workflow is often as shown in Fig. 2. Note that the more realistic workflow has more iterative aspects than the ideal. Models are crafted and difficult to construct in a single shot. When multiple projects are done that analyze the same supply chain the workflow will actually look like Fig. 3.

What Are the Challenges in the Business Process

Because so many scenarios can be required due to the options available, to test many inputs, and do sensitivities, it is a challenge to track and organize the information going into and coming out of the various scenarios. Therefore having sound organizational skills is critical. Further, in this type of project, there are always new options and sensitivities that can be devised. This means timeline management is critical, as is the ability to limit scope creep. These types of issues are not unique to aggregate planning projects, and can be addressed with solid project management.

Who Is Needed for the Project Team

In order for the project to be successful, the right project team needs to be assembled

Figure 1. Ideal Work Flow.

Figure 2. Realistic Work Flow.

that covers the right skill sets. Obviously, one member of the team needs to be a modeler. The modeler requires technical skills, business skills, and communication skills. The technical skills include first an understanding of the mathematics that the software is using. The modeler also requires skills in using spreadsheets and data bases at an above average level. The information that is normally supplied in aggregate planning projects does not come from a

single unified source. It is typically found in many fragments in different data bases and spreadsheets. The modeler has to be able to effectively and efficiently rearrange and process the data into a form that the software can use. It is strongly preferred that the modeler should also be able to develop automation, for example, macros and shell-scripts, to ensure accuracy and repeatability in the data processing, in using the modeling software, and in the report

Figure 3. Realistic Multi-Project Work Flow.

generation. Further the modeler needs to have some understanding of the business. This is required so that the model structure properly captures the key elements of the

real life system that will drive the decisions that the project is required to make. This is also needed so that the modeler can apply the proper judgment of when and how to

approximate different elements of the model. The modeler needs to be able to translate the raw model output into actionable information that explains what is happening in the model and why. The modeler needs to be able to generate the types of reports that quickly and cleanly communicate the results to a wider, and frequently less technical and audience.

A number of area specialists are required. In a supply chain aggregate planning, project specialists in areas such as manufacturing, operations, logistics, and engineering are required. Their participation can be on an as-needed basis. The project will also require a financial specialist because ultimately the decisions are financially driven, so financial analysis will be a key part of the final decisions.

Finally, the project team requires a project manager. This person does not require as much technical skills as the modeler, but they are vital in the role of maintaining timelines, information flow, contacts, and team coordination. In this manner an aggregate planning project is not different from any other project where sound project management is required for success. The project manager may also supply some amount of the analysis on the project. The exact split between the analysis done by the modeler and the project manager largely depends on the technical skills and business knowledge of both. The best results are arrived when the final analysis is the product of a good set of interaction among the team members. Finally, someone in the team needs to have presentation skills to communicate out the results of the overall analysis. This would often be the project manager, though it is not required that they be the only presenter. If any of these skill sets are lacking, then no matter how sound the underlying mathematics, the project is in danger of not being successful.

DATA PROCESS

What Is the Data Process

The data process is the process to get the information needed for the aggregate plan, for example, obtaining the data for demand, production, logistics, and so on. Similar to

the business process, the data process is an area that tends to cause more issues than the mathematics. Getting good data that is clean in a format that can be used is key in constructing an aggregate plan but difficult in practice. Related to this is the ability to track the data that is going into multiple scenarios to maintain the traceability of assumptions.

What Are the Challenges in the Data Process

There are several challenges in the data process. One is that readily available data is typically from the financial tracking system. The issue is that cost accounting standards are often not designed for purposes of an aggregate plan. For example, an aggregate plan usually requires variable costs of production by product by site. Cost accounting standards that are developed for production by product by site may have allocated fixed costs or allocated over time labor costs. This means that making an incremental unit of product would not actually increase the total spend of the supply chain by the amount that is indicated in the cost standard.

Another challenge is simply having errors buried in the data. Optimization models are very good at finding the bad data. Unfortunately this is not a beneficial feature. Any information that is incorrectly cheap will be exploited by the model and then produce a false positive with respect to financial benefits. Any information that is incorrectly expensive will be avoided by the model so that good and reasonable solutions will not be used due to an error in the data.

What Can be done about the Challenges in the Data Process

The first step in dealing with the issues in the data process is simply to be prepared to invest the time to understanding what is in the data, what assumptions went into creating the data, and in identifying and correcting errors. This is best done up front in the project. Another good practice is to avoid inheritance, where one project inherits data or structure from a previous project back several generations. If a model is used on multiple projects, there should be a clear

well documented schema for the input in the current version of the model. What should be avoided is to have legacy numbers whose origin is currently unknown that were added to the model in a previous project where traceability has been lost.

Ideally the customers (internal or external) for the results of an aggregate planning exercise will be the same group that is supplying the most important inputs. This gives the group that understands the data the best the motivation for cleaning the data. This also sets up a feedback loop on the data, providing a natural incentive to balance the demands of accuracy versus the effort that can be saved in obtaining data by using approximations.

A significant amount of time is needed to analyze the results that come out of the aggregate plan. Errors that were not detected in the input can be found in understanding the behavior of the output. Therefore, it is helpful to the data process to trace the drivers that explain the behavior of particular scenarios. Again, being able to generate reports quickly and accurately that illuminate model behavior is useful since it aids in identifying the drivers. This needs to be done not just to understand what the model is doing but also what the model is NOT doing. Understanding the business to understand the reasonableness of the results is critical.

Finally a number of types of automation are incredibly useful. Automation of the data processing, of creation of scenarios, and of the output generation is profoundly useful in maintaining the consistency and quality of the results. As assumptions change or different option combinations are needed they can be handled in a nonmanual manner. A manual process can be risky, reckless, and error prone. They are also the most difficult to debug. This is the same as the difference between trying to add a long column of numbers with a calculator versus using a spreadsheet.

DECISION PROCESS

What Is the Decision Process

The decision process is simple the way that the aggregate planning analysis is used in

making a decision or a set of decisions. This can involve two types of questions—absolute and relative. Relative questions are where there is a base case scenario and an alternative scenario and the question is which one is better and by how much. This is the preferred type of question to answer because the model will not match real life, but in comparing two scenarios the biases of the model will tend to cancel. Absolute questions are where no comparison is made and the absolute values from a single scenario are used. An example of a relative question is “What is the decrease in costs due to adding a production line in plant X?” An example of an absolute question is “How many months during the year would that production line have utilization > 80%?”

What Are the Challenges in the Decision Process

The first difficulty in the decision process is to persuade the decision makers that an aggregate model should be part of the decision process. If it is not then frequently the decisions are based on the rules of thumb, which put a very real limit on the number and types of options that are explored. This also limits the thoroughness and due diligence that can be applied. The thoroughness of a model means that it can be used to uncover approaches that a person may overlook.

Once aggregate planning is part of the decision process, it is important to be clear on the purpose of the model. The point of an aggregate plan for strategic purposes is to determine what is the optimal course of action GIVEN a set of assumptions, not to determine how likely those assumptions are to be true. It is important to use an aggregate model for the purpose for which it was designed. More than that, each individual model and scenario is designed for a specific question, so it is important to craft the model for that question. If this is neglected then the risk is that modeling may be done for the sake of modeling and not to add value to the decision process.

On the other hand, once aggregate planning has gained acceptance, there is the danger of having an over dependence on it. It can become a substitute for judgment and not a means to augment judgment in the decision

making process. There is also the danger that because a specific aggregate plan covers a wide scope of aspects of a supply chain that it will be used to answer questions about everything in that scope. For example, a model may be intended to answer production questions, so it is designed with production data with significant detail and logistics data at only high level approximations. The tendency is to try to use the same model for both production and logistics questions despite the design intent.

In other words:

1. Without strategy, there is only drift.
2. You cannot predict the future. You can only prepare for it.

3. Models are only a means to answering a question. What is the question?
4. Models inform strategic decisions. They do not make them.
5. The only universal model is reality.

AGGREGATION AND LUMPING OF DTMCs¹

MARLIN U. THOMAS

Wright-Patterson AFB, Ohio

Markov chains are fundamental in operations research modeling, ranking among the most applied methodologies in the field. Markov decision processes, queueing networks, and inventory systems are examples of OR/MS modeling platforms that are based on Markov chains. This is due largely to the appeal and practicality of the embedded Markov property along with the computational simplicity provided by the Chapman–Kolmogorov equations. Another attraction is the robustness and flexibility that can sometimes be gained by working with functions of Markov chains that can simplify the structure and analysis procedures.

This article provides an overview of the methods and conditions for transforming discrete time Markov chains (DTMCs) into a smaller process with fewer states by partitioning the state space into subsets each of which can be treated as a single state. Burke and Rosenblatt [1] discovered, through their early more general investigations of functions of Markov chains, conditions for which an ergodic Markov chain can be partitioned to form a smaller chain with transition probabilities that satisfy the Chapman–Kolmogorov equations for arbitrary choices of initial probability vectors. Their seminal finding initiated the development and established the foundation for lumpability theory.

MARKOV CHAIN LUMPABILITY

Lumpability is the process of partitioning the state space of a Markov chain into subsets each of which can be treated as a single state of a smaller chain that retains the Markov property. Consider a DTMC $\{X_t : t = 0, 1, \dots\}$ with finite state space $\Omega = \{1, 2, \dots, n\}$, stationary transition probability matrix $P = [p_{ij}]$, where $i, j = 1, \dots, n$, and initial state probability vector $\mathbf{p}^0 = (p_1^0, \dots, p_n^0)$.

Let $\tilde{\Omega} = \{L_1, L_2, \dots, L_m\}$ be a nontrivial partition of Ω into $m < n$ subsets.

Strong Lumpability

Definition 1. $\{X_t\}$ is strongly lumpable with respect to $\tilde{\Omega}$ if for every initial state probability vector $\mathbf{p}^0$, the resulting chain, $\{\tilde{X}_t\}$ is Markov with transition probability matrix $\tilde{P} = [\tilde{p}_{ij}]$, $i, j = 1, 2, \dots, m$, that is invariant under choices of $\mathbf{p}^0$.

The criterion for establishing that a given Markov chain is lumpable is based on whether the particular partition $\tilde{\Omega}$ of the state space will result in $\tilde{P}$ that satisfies the Chapman–Kolmogorov equations. This forms the basis for the following conditions for strong lumpability

Theorem 1. [Ref. 2, Theorem 6.3.2]. A necessary and sufficient condition for a DTMC $\{X_t : t = 0, 1, \dots\}$ on $\Omega = \{1, 2, \dots, n\}$ with transition probability matrix $P = [p_{ij}]$ to be strongly lumpable with respect to $\tilde{\Omega} = \{L_1, \dots, L_m\}$, $m < n$, for each pair (L_i, L_j) is

$$\tilde{p}_{ij} = \sum_{r \in L_j} p_{kr}, \text{ for any } k \in L_i \quad (1)$$

Corollary 1. If $\{X_t\}$ is ergodic and $\pi = (\pi_1, \pi_2, \dots, \pi_n)$ is the limiting probability distribution, then

$$\tilde{\pi}_j = \sum_{r \in L_j} \pi_r, j = 1, \dots, m \quad (2)$$

is the corresponding limiting probability distribution for the lumped chain.

Example 1. Consider the DTMC with the transition probability matrix

$$P = \begin{bmatrix} 0.3 & 0.2 & 0.2 & 0.2 & 0.1 \\ 0.1 & 0.4 & 0.2 & 0.2 & 0.1 \\ 0 & 0.2 & 0.5 & 0 & 0.3 \\ 0 & 0.3 & 0.1 & 0.2 & 0.4 \\ 0.3 & 0 & 0.1 & 0.3 & 0.3 \end{bmatrix}.$$

It follows by inspection that this chain is lumpable with respect to $\tilde{\Omega} = \{(1, 2), 3, (4, 5)\} = \{L_1, L_2, L_3\}$. Thus from Equation (1)

$$\begin{aligned} p_{11} + p_{12} &= p_{21} + p_{22} & p_{13} &= p_{23} \\ p_{14} + p_{15} &= p_{24} + p_{25} \\ p_{41} + p_{42} &= p_{51} + p_{52} & p_{43} &= p_{53} \\ p_{44} + p_{45} &= p_{54} + p_{55} \end{aligned}$$

therefore,

$$\begin{aligned} \tilde{P} &= \begin{bmatrix} p_{11} + p_{12} & p_{13} & p_{14} + p_{15} \\ p_{31} + p_{32} & p_{33} & p_{34} + p_{35} \\ p_{41} + p_{42} & p_{43} & p_{44} + p_{45} \end{bmatrix} \\ &= \begin{bmatrix} 0.5 & 0.2 & 0.3 \\ 0.2 & 0.5 & 0.3 \\ 0.3 & 0.1 & 0.6 \end{bmatrix}. \end{aligned}$$

It can be shown that the limiting probability distribution for the original chain is $\pi = (0.14, 0.21, 0.22, 0.18, 0.25)$ and for the lumped chain from Equation (2), $\tilde{\pi} = (0.35, 0.22, 0.43)$.

An equivalent characterization of strong lumpability that can be useful in examining lumpability options is given by the following.

Corollary 2. $\{X_t\}$ is strongly lumpable to $\{\tilde{X}_t\}$ if and only if there exist matrices A and B such that

$$BAPB = PB, \quad (3)$$

where $B = [b_{ij}]$ with

$$b_{ij} = \begin{cases} 1, & i \in L_j \\ 0, & i \notin L_j, \end{cases} \quad i = 1, 2, \dots, n; \quad j = 1, 2, \dots, m,$$

and $A = (B'B)^{-1}B'$.

The position of the 1s in each column of B correspond to the subset of states in Ω that form a lumped state in $\tilde{\Omega}$. It follows that if Equation (3) is satisfied then the transition probability matrix for the lumped chain is given by

$$\tilde{P} = APB. \quad (4)$$

Matrices A and B are the distributor and aggregator matrices, and it follows that they are useful in deriving properties of interest for the lumped process, which include the following:

1. Since $AB = I$, the s -step state transition probability matrix for the lumped chain is

$$\tilde{P}^s = AP^s B. \quad (5)$$

2. Given $\{X_t\}$ has the limiting state probability distribution π , the limiting state probability distribution for $\{\tilde{X}_t\}$ is given by

$$\tilde{\pi} = \pi B. \quad (6)$$

3. If $\mathbf{p}^0$ is the initial state probability vector for the original chain, then for the lumped chain

$$\tilde{\mathbf{p}}^0 = \mathbf{p}^0 B. \quad (7)$$

The proofs for these results follow directly from the fact that $AB = I$ and Equation (4).

Example 1 (continued). To apply the matrix operations for the lumped chain in Example 1, from Equation (3)

$$B = \begin{bmatrix} 1 & 0 & 0 \\ 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \\ 0 & 0 & 1 \end{bmatrix}$$

and

$$A = (B'B)^{-1}B'$$

$$= \begin{bmatrix} 1/2 & 1/2 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 1/2 & 1/2 \end{bmatrix}.$$

From Equation (4), it follows that

$$\tilde{P} = \begin{bmatrix} 1/2 & 1/2 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 1/2 & 1/2 \end{bmatrix}$$

$$\times P \begin{bmatrix} 1 & 0 & 0 \\ 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \\ 0 & 0 & 1 \end{bmatrix}$$

$$= \begin{bmatrix} 0.5 & 0.2 & 0.3 \\ 0.2 & 0.5 & 0.3 \\ 0.3 & 0.1 & 0.6 \end{bmatrix},$$

and from Equation (6), $\tilde{\pi} = \pi B = (0.35, 0.22, 0.43)$.

While the necessary and sufficient conditions of Theorem 1 and Corollary 2 for Markov chain lumpability provide useful means of establishing or confirming that a particular choice of $\tilde{\Omega}$ qualifies for $\{X_t\}$ being a lumped chain, there is a major challenge in efficiently finding these choices. Moreover, for parent DTMCs with large state spaces the related combinational problem can be insurmountable. The following approach provides useful guidance for finding alternative lumpings.

Approach for Generating Alternative Lumpings

Operationally, lumping involves taking linear functions of the parent transition probability matrix P that will satisfy the necessary and sufficient conditions (1) and (4) for suitable choices of $\tilde{\Omega}$ for which the associated transition probability matrix $\tilde{P}$ will satisfy the Chapman–Kolmogorov equation. To this end, the following results for the geometric properties of DTMCs provide useful guidance in developing lumping options [3].

We consider a process of systematically prescribing alternative lumpings by generating matrices B for a given transition probability matrix P on Ω . Consider the left

eigenvectors of P such that for λ an eigenvalue, $xP = x\lambda$, $x \neq 0$. So for $\lambda = 1$, the corresponding positive unit-eigenvector is the limiting state probability distribution π of $\{X_t\}$. The remaining eigenvectors corresponding to eigenvalues other than 1, are orthogonal to the vector $\mathbf{1} = (1, \dots, 1)$.

The procedure incorporates results from [3] on the eigenvector structure of P . Let $\{X_t\}$ be a DTMC with transition probability matrix P that is lumpable to $\{\tilde{X}_t\}$ with transition probability matrix $\tilde{P}$.

1. The eigenvalues of $\tilde{P}$ are eigenvalues of P .
2. For left eigenvector x associated with eigenvalue λ of P , $(xB)\tilde{P} = (xB)\lambda$.
3. If λ is *not* an eigenvalue of $\tilde{P}$, then $xB = 0$.

The problem of searching for alternative lumpings from Corollary 2 can be treated as that of finding B matrices that satisfy Equation (3).

Example 2. Consider the simple Markov chain with the transition probability matrix

$$P = \begin{bmatrix} 0.3 & 0.2 & 0.5 \\ 0.4 & 0.5 & 0.1 \\ 0.4 & 0.4 & 0.2 \end{bmatrix}.$$

The eigenvalues λ^j and associated eigenvectors, x^j , $j = 1, 2, 3$, for P are

$$\lambda^1 = -0.1 : x^1 = (-0.5, -0.5, 1)$$

$$\lambda^2 = 0.1 : x^2 = (0, -1, 1)$$

$$\lambda^3 = 1 : x^3 = (-1, -1, -0.75)$$

Applying Result 3 and generating the matrix

$$B = \begin{bmatrix} 1 & 0 \\ 0 & 1 \\ 0 & 1 \end{bmatrix},$$

$x^1B = (-0.5, 0.5)$, $x^2B = (0, 0)$, and $x^3B = (-1, 0)$. Therefore, $\tilde{\Omega} = \{1, (2, 3)\}$ is a “candidate” lumping of $\Omega = \{1, 2, 3\}$. Since Equation (3) is satisfied,

$$\tilde{P} = \begin{bmatrix} 0.3 & 0.7 \\ 0.4 & 0.6 \end{bmatrix}$$

with eigenvalues and vectors $\tilde{\lambda}^1 = -0.1$, $\tilde{x}^1 = (-0.5, 0.5)$; $\tilde{\lambda}^2 = 1$, $\tilde{x}^2 = (-0.1, -1.75)$.

Results 1–3 are incorporated into the following procedure for generating alternative lumpings for a DTMC $\{X_t\}$.

Barr–Thomas Algorithm

1. Compute eigenvalues of P : $\lambda_1 \leq \lambda_2 \leq \dots \leq \lambda_n = 1$.
2. For each λ^j compute left eigenvectors $x^j = (x_1^j, x_2^j, \dots, x_n^j)$.
3. Generate B such that $x^j B = 0$, $j = 1, \dots, n-1$.
4. Compute A from $AB = I$ and $\tilde{P} = APB$.
5. Check the eigenvalues of $\tilde{P}$.

The ordering of the eigenvalues in Step 1 is not necessary but is generally convenient. Since P and $\tilde{P}$ are stochastic matrices, $\lambda = 1$ will always be an eigenvalue and the associated eigenvector can be normalized to give the steady state probability vector π and $\tilde{\pi}$. So the value $\lambda = 1$ can be eliminated from consideration in generating B matrices. It should also be noted that in Step 3, it is possible to have multiple B matrices that satisfy $x^j B = 0$. Thus, since the B matrices satisfying the condition are not unique Step 5 is necessary. If one of the eigenvalues $\tilde{\lambda}_1 \leq \tilde{\lambda}_2 \leq \dots \leq \tilde{\lambda}_m = 1$, $m < n$ is not found among the λ_j s in Step 1, then a different choice of B should be examined [4].

Example 3. As a final illustration of the algorithm consider the Markov chain in Example 1 with

$$P = \begin{bmatrix} 0.3 & 0.2 & 0.2 & 0.2 & 0.1 \\ 0.1 & 0.4 & 0.2 & 0.2 & 0.1 \\ 0 & 0.2 & 0.5 & 0 & 0.3 \\ 0 & 0.3 & 0.1 & 0.2 & 0.4 \\ 0.3 & 0 & 0.1 & 0.3 & 0.3 \end{bmatrix}$$

Starting with Steps 1 and 2, all of the eigenvalues and associated eigenvectors for

Table 1. Eigenvalues and Eigenvectors for P in Example 1

j	λ_j	Eigenvectors, x^j				
1	-0.1	1	-1	0	1	-1
2	0.2	1	-1	0	0	0
3	0.3	-0.1	0.3	-0.2	0.1	-0.1
4	0.3	-0.1	0.3	-0.2	0.1	-0.1
5	1	0.14	0.21	0.22	0.18	0.25

P are given in Table 1. Continuing in Step 3 with eigenvalue $\lambda_1 = -0.1$ and corresponding vector $x^1 = (1, -1, 0, 1, -1)$,

$$B = \begin{bmatrix} 1 & 0 & 0 \\ 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \\ 0 & 0 & 1 \end{bmatrix}.$$

In Step 4, computing A and then from Equation (4),

$$\tilde{P} = \begin{bmatrix} 0.5 & 0.2 & 0.3 \\ 0.2 & 0.5 & 0.3 \\ 0.3 & 0.1 & 0.6 \end{bmatrix}.$$

Checking the eigenvalues of $\tilde{P}$, $\tilde{\lambda}_1 = -0.1$, $\tilde{\lambda}_2 = 0.3$, and $\tilde{\lambda}_3 = 1$, from which it follows from Corollary 2 that this choice of B is an alternative lumping with the partition $\tilde{\Omega} = \{(1, 2), 3, (4, 5)\}$.

Weak Lumpability

Strong lumpability is a useful theoretical construct for Markov chain modeling but it is generally too restrictive for practical applications. A less restrictive form of lumpability, apparently conceived by Burke and Rosenblatt [1] and Kemeny and Snell [2] requires that the transition probability matrix $\tilde{P}$ on the partitioned state space $\tilde{\Omega}$ satisfy the Chapman–Kolmogorov equation for only selected initial probability vectors. One of these vectors will be the steady state probability vector. Formally, as with strong lumpability we consider a DTMC $\{X_t : t = 0, 1, \dots\}$ with finite state space $\Omega = \{1, 2, \dots, n\}$, stationary transition probability matrix $P = [p_{ij}]$, $i, j = 1, \dots, n$, and $\tilde{\Omega} = \{L_1, L_2, \dots, L_m\}$ is a nontrivial partition

of Ω into $m < n$ subsets. Let $\mathbf{A}$ denote the set of all initial probability vectors.

Definition 2. $\{X_t\}$ is weakly lumpable with respect to $\tilde{\Omega}$ if for selected initial state probability vectors $\alpha^{(k)} \in \mathbf{A}$ the resulting chain, $\{\tilde{X}_t\}$, is Markov with transition probability matrix $\tilde{P} = [\tilde{p}_{ij}]$, $i, j = 1, 2, \dots, m$.

The major problem in establishing strong lumpability is in finding alternative lumpings for a given DTMC. While weak lumpability is a less restrictive condition, it is further complicated by the need for finding suitable initial probability vectors for which the Chapman–Kolmogorov equation holds.

The basic framework for examining weak lumpability conditions originated with the early work of Kemeny and Snell [2]. They showed that some but not necessarily all initial probability vectors $\alpha \in \mathbf{A}$ will permit the aggregated chain $\tilde{X}_t = \text{agg}(\alpha, P, \tilde{\Omega})$ to satisfy the Chapman–Kolmogorov equation. Moreover, the transition probability matrix for the lumped chain, $\tilde{P}$, will be the same for all such $\alpha \in \mathbf{A}$ that do result in a Markov chain. The challenge is in finding such a set of initial probability vectors. Abdel-Moneim and Leysieffer [5] introduced an approach for characterizing weak lumpability that was perfected and extended by Rubino and Sericola [6,7] to provide a procedure for computing the set of initial probability vectors that will lead to lumpable Markov chains.

Denoting the aggregated chain from (α, P) over a partition $\tilde{\Omega} = \{L_1, \dots, L_m\}$, $m < N$ by $\text{agg}(\alpha, P, \tilde{\Omega})$, and the cardinality of L_i by $\kappa(i)$, the partitioned subsets can be written as

$$\begin{aligned} L_1 &= \{1, \dots, \kappa(1)\} \\ &\dots \\ L_j &= \{\kappa(1) + \dots + \kappa(j-1) \\ &\quad + 1, \dots, \kappa(1) + \dots + \kappa(j)\}. \\ &\dots \\ L_m &= \{\kappa(1) + \dots + \kappa(m-1) + 1, \dots, N\} \end{aligned}$$

For $L \subseteq \Omega$ and $\sum_{j \in L} \alpha(j) \neq 0$ the vector α^L of $\mathbf{A}$ is defined by

$$\alpha^L(i) = \begin{cases} \alpha(i) / \sum_{j \in L} \alpha(j), & i \in L \\ 0, & i \notin L \end{cases}. \quad (8)$$

Further denote for each $\ell \in \Omega$ and $\alpha \in \mathbf{A}$ the vector $T_\ell \cdot \alpha$ having $\kappa(\ell)$ elements as the restriction of α corresponding to the subset L_ℓ . To illustrate this notation, consider the DTMC in Example 1 for which $N = 5$ and $L = \{L_1, \dots, L_3\}$ with $L_1 = \{1, 2\}$, $L_2 = \{3\}$, and $L_3 = \{4, 5\}$. So for $\alpha = \pi = (0.14, 0.21, 0.22, 0.18, 0.25)$:

$$\begin{aligned} \alpha^{L_1} &= (.4, .6, 0, 0, 0), \quad T_1 \cdot \alpha^{L_1} = (.4, .6) \\ \alpha^{L_2} &= (0, 0, 1, 0, 0), \quad T_2 \cdot \alpha^{L_2} = (1) \\ \alpha^{L_3} &= (0, 0, 0, .42, .58), \\ T_3 \cdot \alpha^{L_3} &= (0.42, 0.58) \end{aligned}$$

The Rubino–Sericola procedure for finding the set of initial probability vectors,

$$\mathbf{A}_M = \{\alpha \in \mathbf{A} | \tilde{X}_t = \text{agg}(\alpha, P, \tilde{\Omega}) \text{ is a Markov chain}\}$$

is based on the following conditions. Let

$$\mathbf{A}^1 = \{\alpha \in \mathbf{A} | (T_\ell \cdot \alpha^{L_\ell}) \tilde{P}_1 = \hat{P}_\ell, \forall \ell \in \tilde{\Omega}\}$$

and

$$\mathbf{A}^j = \{\alpha \in \mathbf{A} | \beta = f(\alpha; L_1, \dots, L_k), \\ k \leq j, \beta \in \mathbf{A}^1, j \geq 2\}.$$

1. If $\tilde{P}$ is the transition probability matrix for the aggregated Markov chain $\tilde{X} = \text{agg}(\alpha, P, \tilde{\Omega})$ then $\tilde{P}$ is the same for every α leading to an aggregated Markov chain [2].
2. $\mathbf{A}_M \neq \emptyset$ iff $\mathbf{A}^1$ is stable by right product by P (i.e., subset U is stable by right product by P iff $\forall u \in U$ vector uP is an element of U), thus $\mathbf{A}_M = \mathbf{A}^1$ [6].
3. $\mathbf{A}_M$ is a convex closed set [6].

Now for $\ell \in \Omega$ denote by $\hat{P}_\ell$ the probability of transitions in one step from state j in L_ℓ to L_m which is the $\kappa(\ell) \times m$ matrix defined by

$$\begin{aligned} \hat{P}_\ell(j, m) &= P\{\kappa(1) + \dots + \kappa(\ell-1) \\ &\quad + j, L_m\}, \quad 1 \leq j \leq \kappa(\ell), m \in \tilde{\Omega}. \end{aligned} \quad (9)$$

It follows that $\hat{P}_\ell$ is the ℓ th row vector of the transition probability matrix for the lumped chain $\hat{P}$. When $\mathbf{A}_M \neq \emptyset$, $\hat{P}$ is the same for all $\alpha \in \mathbf{A}_M$ and can be computed by $\tilde{P}_\ell = (T_\ell \cdot \alpha^{L_\ell}) \hat{P}_\ell$.

Example 1 (continued). Applying this procedure to the DTMC in Example 1,

$$\begin{aligned}\hat{P}_1 &= \begin{pmatrix} 0.5 & 0.2 & 0.3 \\ 0.5 & 0.2 & 0.3 \end{pmatrix}, \\ \hat{P}_2 &= (0.2 \quad 0.5 \quad 0.3), \\ \hat{P}_3 &= \begin{pmatrix} 0.3 & 0.1 & 0.6 \\ 0.3 & 0.1 & 0.6 \end{pmatrix},\end{aligned}$$

from which it follows that

$$\begin{aligned}\tilde{P}_1 &= (T_1 \cdot \alpha^{L_1}) \hat{P}_1 \\ &= (0.4, 0.6) \begin{pmatrix} 0.5 & 0.2 & 0.3 \\ 0.5 & 0.2 & 0.3 \end{pmatrix} \\ &= (0.5, 0.2, 0.3).\end{aligned}$$

and similarly, $\tilde{P}_2 = (0.2, 0.5, 0.3)$, $\tilde{P}_3 = (0.3, 0.1, 0.6)$, and

$$\tilde{P} = \begin{pmatrix} 0.5 & 0.2 & 0.3 \\ 0.2 & 0.5 & 0.3 \\ 0.3 & 0.1 & 0.6 \end{pmatrix}.$$

The set of initial probability vectors that lead to a time homogeneous Markov chain, $\mathbf{A}^1$ and $\mathbf{A}^j$, $j \geq 2$, is derived through the following recursive operations. Let $\beta_j = P\{X_t = j | X_t \in L_t, \dots, X_0 \in L_0\}$ and for $\alpha \in \mathbf{A}$ define the vector $\beta_k = f(\alpha; L_1, \dots, L_k) \in \mathbf{A}$ and the recursive relationship:

$$\begin{aligned}f(\alpha; L_1) &= \alpha^{L_1} \\ f(\alpha; L_1, L_2) &= (\alpha^{L_1} P)^{L_2} \\ &\dots \\ f(\alpha; L_1, \dots, L_k) &= f(\alpha; L_1, \dots, L_{k-1}) P^{L_k}\end{aligned}\tag{10}$$

Example 4. [from Ref. 6]. Consider the Markov chain $\{X_t\}$ with one-step transition matrix

$$P = \begin{bmatrix} 1/6 & 1/6 & 1/6 & 1/2 \\ 1/8 & 3/8 & 1/4 & 1/4 \\ 3/8 & 1/8 & 1/4 & 1/4 \\ 1/4 & 1/4 & 1/4 & 1/4 \end{bmatrix},$$

with the alternative aggregated partition $\tilde{\Omega} = \{L_1, L_2\}$, $L_1 = (1, 2, 3)$, $L_2 = (4)$. Note that the chain is not strongly lumpable since $p_{14} = 1/2 \neq p_{24} = 1/4$. Applying Equation (6) for the limiting probability distribution $\pi = (3/13, 3/13, 3/13, 4/13)$,

$$\begin{aligned}\pi_1^{L_1} &= (1/3, 1/3, 1/3, 0), \\ \pi_1^{L_1} P &= (2/9, 2/9, 2/9, 1/3) \\ \pi_2^{L_1} &= (0, 0, 0, 1), \\ \pi_2^{L_1} P &= (0, 0, 0, 1)\end{aligned}$$

It follows that

$$\hat{P}_1 = \begin{pmatrix} 1/2 & 1/2 \\ 3/4 & 1/4 \\ 3/4 & 1/4 \end{pmatrix}, \quad \hat{P}_2 = (3/4, 1/4)$$

from which it follows that

$$\begin{aligned}\tilde{P}_1 &= (T_1 \cdot \alpha^{L_1}) \hat{P}_1 \\ &= (1/3, 1/3, 1/3) \begin{pmatrix} 1/2 & 1/2 \\ 3/4 & 1/4 \\ 3/4 & 1/4 \end{pmatrix} \\ &= (2/3, 1/3).\end{aligned}$$

and similarly, $\tilde{P}_2 = (3/4, 1/4)$, and

$$\tilde{P} = \begin{pmatrix} 2/3 & 1/3 \\ 3/4 & 1/4 \end{pmatrix}.$$

Now to construct $\mathbf{A}^1$, applying Equation (10)

$$\begin{aligned}f(\alpha; L_1) &= \alpha^{L_1} = (1/3, 1/3, 1/3, 0) \\ f(\alpha; L_1, L_2) &= (f(\alpha; L_1) P)^{L_2} \\ &= (2/9, 2/9, 2/9, 1/3)^{L_2} = (0, 0, 0, 1).\end{aligned}$$

It follows that

$$\begin{aligned}\mathbf{A}^1 &= \{\alpha \in \mathbf{A} | (T_1 \cdot \alpha^{L_1}) \tilde{P}_1 = \hat{P}_1, (T_2 \cdot \alpha^{L_2}) \\ &\quad \times \tilde{P}_2 = \hat{P}_2\},\end{aligned}$$

$$(\sigma_1, \sigma_2, \sigma_3) \begin{pmatrix} 1/2 & 1/2 \\ 3/4 & 1/4 \\ 3/4 & 1/4 \end{pmatrix} = (2/3, 1/3),$$

thus leading to $\mathbf{A}^1 = \{\lambda (\frac{1}{3}, t, \frac{2}{3} - t) + (1 - \lambda) (0, 0, 0, 1), 0 \leq t \leq 2/3, 0 \leq \lambda \leq 1\}$.

Further details on weak lumpability can be found in Refs 2, 6–8. As with the case for strong lumpability, the current

theory does not provide a simple procedure for identifying and generating potential lumping which restricts the applications in operations research. Ledoux [9,10] has developed some interesting and promising results based on the geometric properties associated with weak lumpability. He established the equivalence of weak lumpability with the existence of a direct sum of polyhedral cones that is positively invariant by the transition probability matrix of the parent chain. This will hopefully lead to further results and insights for finding efficient algorithms for identifying lumping options.

STATE AGGREGATION

When the state space of a DTMC is very large even though numerous possible lumping can exist, the restrictive theory of lumpability does not provide easy methods for efficiently identifying and examining lumpability. Therefore, state space aggregation generally produces smaller chains that lack the Markov property and are therefore only approximations to the parent Markov Chain. In this context, lumpability can be thought of as a special case of state space aggregation where the aggregated chain is Markov. Still, lumpability theory provides the basis for developing approximation methods for computing the various measures of interest for the parent Markov chain from the aggregated chain.

The objective of state space aggregation methods is to determine the various stationary and transient results such as state probabilities, sojourn times, and mean passage times from a decomposed or aggregated chain. Takahashi [11] developed an iterative aggregation–disaggregation (IAD) procedure for Markov chain analysis by state space aggregation. This method involves computing the ergodic probabilities through an iterative process of allocating lumping of states to individual states, alternately solving an aggregated system and a disaggregated system. Schweitzer [12] extended the algorithm with a process that would ensure geometric convergence of the state probability vector computation, and further showed that for the special case of the DTMC being

weakly lumpable (called “exactly lumpable”), the IAD algorithm would converge in one step. Sumita and Rieders [13] further showed that for cases where a DTMC is lumpable, the aggregation element of the IAD procedure can be eliminated. For more details on state space aggregation methods see Refs 14–19.

SUMMARY REMARKS

State space aggregation is the process of partitioning the state space of a Markov chain and combining groups of states to form a smaller chain. Lumpability is the special case whereby the resulting smaller chain retains the Markov property as evidenced by the transition probability matrix of the lumped chain satisfying the Chapman–Kolmogorov equations. The degree of lumpability, that is, strong versus weak will depend on whether the Markov condition holds for all or selected initial state probability vectors. There are three motivations for lumpability. First is in structuring Markov models. The Markov dependence and geometric distributed sojourn times that are inherent with Markov chains make them appealing in modeling operational systems. It is quite often reasonable and conservative to assume these properties in the absence of a lot of information. So in constructing such models lumpability can provide additional features for selected applications. For example, the state spaces for manpower planning models typically have gradual growth among neighboring states with few if any backward transitions. The transition probability matrices, P , will then have entries about the diagonal with zeros in the off-diagonal positions. Lumpability options are accordingly more prevalent and easy to develop from Equation (3).

A second motivation for lumpability is the computational advantages that can be gained in working with smaller chains. This is particularly beneficial for lumpable chains with very large state spaces. The difficulty, however, is in identifying valid lumpability alternatives. The current theory, albeit complicated, provides necessary and sufficient conditions for examining lumpability for a

given partitioning of the state space. Efficient methods for finding these partitions are lacking. What is needed is a process that, given a Markov chain $\{X_t\}$ on Ω with transition probability matrix P , will generate all exhaustive partitions $\tilde{\Omega}_1, \tilde{\Omega}_2, \dots, \tilde{\Omega}_K$ to which viable lumpings exist.

The third motivation for lumpability is the value in advancing the knowledge and understanding of Markov chains. The focus of this article has been on finite time homogeneous DTMCs which have received most attention in the literature. Other lumpability efforts include Markov chains with denumerable state spaces [20], stationary reversible DTMCs [21,22], pseudo-stationarity [23], nonirreducible chains [24], and continuous time Markov chains [25].

Many reliability systems or components of such systems have random lifetimes that indicate aging properties of these systems or components. Most of these aging properties can be characterized by various stochastic orders. Such characterizations are useful for the identification of the corresponding aging properties and for a better understanding of the meaning of these properties. In this article, we describe such characterizations. The characterizations can be used in practice to develop various inequalities that yield bounds on various probabilistic quantities of interest such as the survival function and moments. Some of these characterizations have been used to provide statistics for testing exponentiality against aging properties [1].

We also often encounter aging notions in the recent operations research and management science literature, in areas other than reliability theory. The common definitions of these aging notions, and the terminology that is associated with them, are usually stated in the language of reliability theory. This is because concepts such as monotone failure rate, monotone residual life, and new better than used (NBU) are meaningful and useful in the context of reliability theory. However, these reliability theoretic concepts are easily grasped by researchers whose expertise lies in areas other than reliability theory. Thus, although reliability theory has “monopolized” the language that is associated with aging notions, it should be

pointed out that, from a mathematical point of view, these notions abound in many other areas of operations research and management science.

Consider, for example, the failure rate notion. Mathematically speaking, this is just the intensity of an occurrence of a particular event (death of an item). Other events that occur randomly in time, in other areas of operations research and management science, also have occurrence intensity. Thus, any statement about failure rates in reliability theory has an analog in other areas. For instance, consider a G/G/1 queue. Arrivals to the queue are occurring randomly in time, and the “failure rates” that correspond to the associated interarrival times are just the arrival intensities. Similarly, the “failure rates” that correspond to the service times are just the end-of-service intensities.

As another example, consider an insured risky asset with a deductible d . The insurer may then be interested in the behavior of the expected claim size as a function of the deductible. For instance, monotonicity of the expected claim amount as a function of d , may be a useful fact. But, in the language of reliability theory, the claim size is just the residual life given that a failure has not occurred before time d . Thus, monotonicity of the expected claim amount in risk management is mathematically the same as the monotonicity of the mean residual life in reliability theory.

Similarly, the residual life at time d has a nice interpretation in reinsurance. It represents the amount paid by the reinsurer in a stop-loss agreement, given that the retention d has been reached (2, p. 124).

An interesting appearance of aging notions occurs in the theory of auctions. In a buyer's auction, the bidder with the highest bid is awarded the goods. Suppose that the valuations of the bidders are independent random variables with some common distribution function. The rent of the winner is the difference between his valuation and the price that he pays. It turns out that if the

common distribution function of the bidders valuations has some aging properties then the expected rent of the winner in a buyer's auction is monotonically decreasing in the number of bidders [3].

Many other instances of aging notions in operations research and management science areas, other than reliability theory, can be listed. We will not do it here.

In this article “increasing” and “decreasing” stand for “nondecreasing” and “non-increasing”, respectively. Expectations are assumed to exist whenever they are mentioned.

SOME STOCHASTIC ORDERS

In this section, we give the definitions of some stochastic orders that will be used in the sequel. Useful references that cover the area of stochastic orders are Refs 4 and 5. Let X and Y be two absolutely continuous nonnegative random variables with distribution functions F and G , survival functions $\bar{F} \equiv 1 - F$ and $\bar{G} \equiv 1 - G$, and density functions f and g . Let F^{-1} and G^{-1} denote the quantile functions of X and Y . Below, the definitions that follow the symbol $\bullet$ are of stochastic orders that can compare any two random variables, whereas the definitions that follow the symbol $\star$ are of stochastic orders that compare nonnegative random variables. The random variable X is said to be smaller than the random variable Y in the

- *ordinary stochastic order* (denoted as $X \leq_{st} Y$) if $\bar{F}(x) \leq \bar{G}(x)$ for all x ;
- *hazard rate order* (denoted as $X \leq_{hr} Y$) if $\bar{F}(x)\bar{G}(y) \geq \bar{F}(y)\bar{G}(x)$ for all $x \leq y$;
- *likelihood ratio order* (denoted as $X \leq_{lr} Y$) if $f(x)g(y) \geq f(y)g(x)$ for all $x \leq y$;
- *mean residual life order* (denoted as $X \leq_{mrl} Y$) if $\bar{G}(x) \int_x^\infty \bar{F}(y) dy \leq \bar{F}(x) \int_x^\infty \bar{G}(y) dy$ for all x ;
- ★ *harmonic mean residual life order* (denoted as $X \leq_{hmrl} Y$) if $(\int_x^\infty \bar{F}(y) dy) / EX \leq (\int_x^\infty \bar{G}(y) dy) / EY$ for all $x \geq 0$;
- *dispersive order* (denoted as $X \leq_{disp} Y$) if $G^{-1}(\alpha) - F^{-1}(\alpha)$ is increasing in $\alpha \in (0, 1)$;

- *excess wealth order* (denoted as $X \leq_{ew} Y$) if $\int_{F^{-1}(\alpha)}^\infty \bar{F}(x) dx \leq \int_{G^{-1}(\alpha)}^\infty \bar{G}(x) dx$ for all $\alpha \in (0, 1)$;
- *location-independent riskier order* (denoted as $X \leq_{lir} Y$) if $\int_{-\infty}^{F^{-1}(\alpha)} F(x) dx \leq \int_{-\infty}^{G^{-1}(\alpha)} G(x) dx$ for all $\alpha \in (0, 1)$;
- *increasing convex order* (denoted as $X \leq_{icx} Y$) if $E[\phi(X)] \leq E[\phi(Y)]$ for all increasing convex functions ϕ for which the expectations are defined;
- *increasing concave order* (denoted as $X \leq_{icv} Y$) if $E[\phi(X)] \leq E[\phi(Y)]$ for all increasing concave functions ϕ for which the expectations are defined;
- *dilation order* (denoted as $X \leq_{dil} Y$) if $X - EX \leq_{icx} Y - EY$;
- ★ *convex transform order* (denoted as $X \leq_c Y$) if $G^{-1}F(x)$ is convex in $x \geq 0$;
- ★ *star order* (denoted as $X \leq_* Y$) if $G^{-1}F(x)$ is starshaped in x ; that is, if $G^{-1}F(x)/x$ increases in $x \geq 0$;
- ★ *superadditive order* (denoted as $X \leq_{su} Y$) if $G^{-1}F(x)$ is superadditive in x ; that is, if $G^{-1}F(x+y) \geq G^{-1}F(x) + G^{-1}F(y)$ for all $x \geq 0$ and $y \geq 0$;
- ★ *Laplace transform order* (denoted as $X \leq_{lt} Y$) if $E[\exp\{-sX\}] \geq E[\exp\{-sY\}]$ for all $s > 0$.

CHARACTERIZATIONS OF AGING PROPERTIES

Throughout this section, X denotes a random variable that may have any of the aging properties that are defined and discussed below. For simplicity of exposition, we assume that X is absolutely continuous with distribution function F , survival function $\bar{F} \equiv 1 - F$, and density function f . For any event A , we use the notation $[X|A]$ to denote any random variable that is distributed according to the conditional distribution of X given A . The results below, as well as additional references, can be found in Ref. 5, unless stated otherwise.

Most of the characterizations in this section are based on stochastic comparisons of residual lives at different times. Another kind of characterizations that we describe

are based on comparisons of the “aging” random variable with an exponential random variable, which in the context of reliability theory, has the “nonaging” property.

For a nonnegative random variable X with a finite mean, let A_X denote the corresponding asymptotic equilibrium age. That is, if the distribution function of X is F then the distribution function F_e of A_X is defined by

$$F_e(x) = \frac{1}{EX} \int_0^x \bar{F}(y) dy, \quad x \geq 0.$$

The asymptotic equilibrium age is of importance in renewal theory. Suppose that we start observing a renewal process, with inter-renewal distribution F , at some time t . Then the process that we end up actually observing is a delayed renewal process, and if t is large, then the distribution of the delay is approximately the distribution of A_X given above. It is also worthwhile to mention that a delayed renewal process, with interrenewal distribution F , with the delay distribution F_e , is a stationary process—this points out another aspect of the importance of the asymptotic equilibrium age. The asymptotic equilibrium age will be used in some characterizations of aging notions below.

The relationships among the aging notions that are characterized below are given in the following chart [1]. The exact definitions of the notions in the chart will be given in the sequel.

$$\begin{array}{ccccc} \text{IFR} & \Rightarrow & \text{IFRA} & \Rightarrow & \text{NBU} \\ \downarrow & & & & \downarrow \\ \text{DMRL} & \Rightarrow & & & \text{NBUE} \Rightarrow \text{HNBUE} \end{array}$$

Increasing and Decreasing Failure Rate (IFR and DFR)

The random variable X is said to have the aging property of increasing failure rate (IFR) if $\bar{F}$ is logconcave. It has the property of decreasing failure rate (DFR) if $\bar{F}$ is logconvex on its support. The ordinary stochastic order can be used to characterize the IFR and DFR notions as follows.

Theorem 1. *The random variable X is IFR [DFR] if, and only if, $[X - t|X > t] \geq_{\text{st}} [\leq_{\text{st}}] [X - t'|X > t']$ whenever $t \leq t'$.*

The hazard rate order can also be used to characterize the IFR and DFR notions:

Theorem 2. *The random variable X is IFR [DFR] if, and only if, one of the following equivalent conditions holds (when the support of X is bounded, condition (iii) does not have a simple DFR analog):*

- (i) $[X - t|X > t] \geq_{\text{hr}} [\leq_{\text{hr}}] [X - t'|X > t']$ whenever $t \leq t'$.
- (ii) $X \geq_{\text{hr}} [\leq_{\text{hr}}] [X - t|X > t]$ for all $t \geq 0$ (when X is a nonnegative random variable).
- (iii) $X + t \leq_{\text{hr}} X + t'$ whenever $t \leq t'$.

Some similar characterizations of IFR and DFR random variables are given in Ref. 6. Other characterizations of IFR and DFR random variables, by means of ordering delayed record value spacings with respect to the order $\leq_{\text{hr}}$, are given in Ref. 7.

Here is how the dispersive order can characterize the IFR and DFR notions [8,9]:

Theorem 3. *The nonnegative random variable X is IFR [DFR] if, and only if, one of the following equivalent conditions holds:*

- (i) $[X - t|X > t] \geq_{\text{disp}} [\leq_{\text{disp}}] [X - t'|X > t']$ whenever $t \leq t'$.
- (ii) $X \geq_{\text{disp}} [\leq_{\text{disp}}] [X - t|X > t]$ for all $t \geq 0$.

Some similar characterizations of IFR and DFR random variables are given in Ref. 6.

Next we describe a result of Ref. 10, which characterizes the IFR and DFR notions by means of the location-independent riskier order:

Theorem 4. *Let X be a random variable with support of the form (a, ∞) , where $a \geq -\infty$ [respectively, $a > -\infty$]. Then X is IFR [DFR] if, and only if, $[X - t|X > t] \geq_{\text{lir}} [\leq_{\text{lir}}] [X - t'|X > t']$ for all $t' > t > a$.*

Another characterization of the IFR and DFR notions is the following [11]:

Theorem 5. *The random variable X is IFR [DFR] if, and only if, $[X - t|X > t] \geq_{\text{icv}} [\leq_{\text{icv}}] [X - t'|X > t']$ whenever $t \leq t'$.*

In some places in the literature, if the condition of Theorem 5 holds, that is, if $[X - t|X > t] \geq_{\text{icv}} [\leq_{\text{icv}}][X - t'|X > t']$ whenever $t \leq t'$, then X is said to have the property of IFR [DFR] in the second-order stochastic dominance (IFR(2) [DFR(2)]). Theorem 5 shows that the IFR(2) [DFR(2)] property is equivalent to the IFR [DFR] property.

Still another characterization, similar to the characterizations in Theorems 1–5, is given in the next theorem [12]:

Theorem 6. *The random variable X is IFR if, and only if, $[X - t|X > t] \geq_{\text{Lt}} [X - t'|X > t']$ whenever $t \leq t'$.*

The convex transform order characterizes the IFR notion as follows. We denote any exponential random variable by Exp (no matter what the mean is).

Theorem 7. *The nonnegative random variable X is IFR if, and only if, $X \leq_c \text{Exp}$.*

Using the notion of the asymptotic equilibrium age, we have the following further characterization of the IFR and DFR concepts:

Theorem 8. *The nonnegative random variable X with a finite mean is IFR [DFR] if, and only if, $X \geq_{\text{lr}} [\leq_{\text{lr}}]A_X$.*

Increasing Failure Rate Average (IFRA)

The nonnegative random variable X is said to have the aging property of increasing failure rate average (IFRA) if $-\log \bar{F}$ is star shaped; that is, if $-\log \bar{F}(t)/t$ is increasing in $t \geq 0$. The main reason for interest in this particular aging notion comes from reliability theory—this notion defines the largest class of distribution functions that are closed with respect to construction of coherent systems. The star order can be used to characterize the IFRA notion as follows. As in Theorem 7, Exp denotes any exponential random variable.

Theorem 9. *The nonnegative random variable X is IFRA if, and only if, $X \leq_* \text{Exp}$.*

New Better (Worse) than Used (NBU and NWU)

The nonnegative random variable X is said to have the aging property of new better than used (NBU) if $\bar{F}(s)\bar{F}(t) \geq \bar{F}(s+t)$ for all $s \geq 0$ and $t \geq 0$. It has the property of new worse than used (NWU) if $\bar{F}(s)\bar{F}(t) \leq \bar{F}(s+t)$ for all $s \geq 0$ and $t \geq 0$. The ordinary stochastic order can be used to characterize the NBU and NWU notions as follows:

Theorem 10. *The random variable X is NBU [NWU] if, and only if, $X \geq_{\text{st}} [\leq_{\text{st}}][X - t|X > t]$ for all $t > 0$.*

Similar to Theorem 7 and 9, the superadditive order can be used to characterize the NBU notion as follows:

Theorem 11. *The random variable X is NBU if, and only if, $X \leq_{\text{su}} \text{Exp}$.*

The order $\leq_{\text{icx}}$ was used in Ref. 13 to define the property of new better than used in convex order (NBUC) as follows. The nonnegative random variable X is said to have the aging property of NBUC if $X \geq_{\text{icx}} [X - t|X > t]$ for all $t > 0$. In fact, earlier, [14] encountered this aging notion, and called it *new better than used in mean (NBUM)*. Using the asymptotic equilibrium age the NBUC aging property can be characterized as follows: X is NBUC if, and only if,

$$X \geq_{\text{st}} [A_X - t|A_X > t] \quad \text{for all } t \geq 0.$$

The order $\leq_{\text{icv}}$ was used in Ref. 15 to define the property of NBU in second-degree stochastic dominance [NBU(2)] as follows. The random variable X is said to have the aging property of NBU(2) if $X \geq_{\text{icv}} [X - t|X > t]$ for all $t > 0$.

Decreasing and Increasing Mean Residual Life (DMRL and IMRL)

The random variable X with a finite mean is said to have the aging property of decreasing mean residual life (DMRL) if $E[X - t|X > t]$ is decreasing in t . It has the property of increasing mean residual life (IMRL) if $E[X -$

$t|X > t]$ is increasing in t . The mean residual life order can be used to characterize the DMRL notion as follows:

Theorem 12. *The random variable X is DMRL if, and only if, one of the following equivalent conditions holds:*

- (i) $[X - t|X > t] \geq_{\text{mrl}} [X - t'|X > t']$ whenever $t \leq t'$.
- (ii) $X \geq_{\text{mrl}} [X - t|X > t]$ for all $t \geq 0$ (when X is a nonnegative random variable).
- (iii) $X + t \leq_{\text{mrl}} X + t'$ whenever $t \leq t'$.

In a similar manner, the order $\leq_{\text{hmrl}}$ can be used to characterize the DMRL notion:

Theorem 13. *The random variable X is DMRL if, and only if, $[X - t|X > t] \geq_{\text{hmrl}} [X - t'|X > t']$ whenever $t \leq t'$.*

Next we describe a characterization of the DMRL and IMRL aging notions by means of the dilation order [8]:

Theorem 14. *The random variable X is DMRL [IMRL] if, and only if, $[X - t|X > t] \geq_{\text{dil}} [\leq_{\text{dil}}] [X - t'|X > t']$ whenever $t \leq t'$.*

Some similar characterizations of DMRL and IMRL random variables are given in Ref. 6.

When the support of X is bounded from below, the excess wealth order can characterize the DMRL and IMRL aging notions as follows [16]:

Theorem 15. *Let X be a continuous random variable with a finite left end point of support $a > -\infty$. Then X is DMRL [IMRL] if, and only if, any one of the following equivalent conditions holds:*

- (i) $[X - t|X > t] \geq_{\text{ew}} [\leq_{\text{ew}}] [X - t'|X > t']$ whenever $t' \geq t \geq a$.
- (ii) $X \geq_{\text{ew}} [\leq_{\text{ew}}] [X - t|X > t]$ for all $t \geq 0$ (when $a = 0$).

Again, some similar characterizations of DMRL and IMRL random variables are given in Ref. 6.

A final result of the type above that we give here uses the order $\leq_{\text{icx}}$ for characterizing the DMRL and IMRL notions [13]:

Theorem 16. *The nonnegative random variable X is DMRL [IMRL] if, and only if, $[X - t|X > t] \geq_{\text{icx}} [\leq_{\text{icx}}] [X - t'|X > t']$ whenever $t \leq t'$.*

There exists an analog of Theorems 7, 9, and 11 for the DMRL aging notion. In order to describe it, we first need to introduce the so-called DMRL stochastic order. The random variable X is said to be *smaller than Y in the DMRL order* (denoted by $X \leq_{\text{dmrl}} Y$) if

$$\frac{\int_{G^{-1}(\alpha)}^{\infty} \bar{G}(x) dx}{\int_{F^{-1}(\alpha)}^{\infty} \bar{F}(x) dx} \text{ is increasing in } \alpha \in [0, 1].$$

Then

Theorem 17. *The nonnegative random variable X is DMRL if, and only if, $X \leq_{\text{dmrl}} \text{Exp}$.*

Li and Li [17] introduced another order, denoted by $\leq_{\text{drlc}}$, such that X is DMRL if, and only if, $X \leq_{\text{drlc}} \text{Exp}$.

Using the notion of the asymptotic equilibrium age, we have the following further characterization of the DMRL and IMRL concepts:

Theorem 18. *The nonnegative random variable X with a finite mean is DMRL [IMRL] if, and only if, $X \geq_{\text{hr}} [\leq_{\text{hr}}] A_X$.*

New Better (Worse) than Used in Expectation (NBUE and NWUE)

The nonnegative random variable X with finite mean is said to have the aging property of new better than used in expectation (NBUE) if $E[X] \geq E[X - t|X > t]$ for all $t \geq 0$. It has the property of new worse than used in expectation (NWUE) if $E[X] \leq E[X - t|X > t]$ for all $t \geq 0$. The harmonic mean residual life order characterizes the NBUE notion as follows:

Theorem 19. *Let X be a nonnegative random variable with positive mean. Then X is NBUE if, and only if, any one of the following equivalent conditions holds:*

- (i) $X \leq_{\text{hmrl}} X + Y$ for any nonnegative random variable Y with a finite positive mean, which is independent of X .
- (ii) $X + Y_1 \leq_{\text{hmrl}} X + Y_2$ whenever Y_1 and Y_2 are almost surely positive random variables with finite means, which are independent of X , such that $Y_1 \leq_{\text{hmrl}} Y_2$.

There exists an analog of Theorems 7, 9, 11, and 17 for the NBUE aging notion. In order to describe it, we first need to introduce the so-called NBUE stochastic order of nonnegative random variables. Let X and Y be nonnegative random variables. Then X is said to be *smaller than Y in the NBUE order* (denoted by $X \leq_{\text{nbue}} Y$) if

$$\frac{1}{EX} \int_{F^{-1}(\alpha)}^{\infty} \bar{F}(x) dx \leq \frac{1}{EY} \int_{G^{-1}(\alpha)}^{\infty} \bar{G}(x) dx$$

for all $\alpha \in [0, 1]$.

Then

Theorem 20. *The nonnegative random variable X is NBUE if, and only if, $X \leq_{\text{nbue}} \text{Exp}$.*

Note that for any two nonnegative random variables Z and W with positive expectations we have $Z \leq_{\text{nbue}} W \iff (Z/EZ) \leq_{\text{ew}} (W/EW)$. Thus, Theorem 20 can be rewritten as follows.

Theorem 21. *The random variable X is NBUE if, and only if, $(X/EX) \leq_{\text{ew}} \text{Exp}(1)$, where $\text{Exp}(1)$ denotes an exponential random variable with mean 1.*

Theorem 1.A.32 in Ref. 5 describes still another similar characterization of the NBUE aging notion using the ordinary stochastic order $\leq_{\text{st}}$.

The asymptotic equilibrium age still gives a further characterization of the NBUE and NWUE concepts:

Theorem 22. *The nonnegative random variable X with a finite mean is NBUE [NWUE] if, and only if, $X \geq_{\text{st}} [\leq_{\text{st}}] A_X$.*

An aging notion that is closely related to the NBUE notion is the notion of the harmonic new better than used in expectation (HNBUE). Formally, the nonnegative random variable X with mean $\mu > 0$ is said to have the aging property of HNBUE if $X \leq_{\text{icx}} \text{Exp}(\mu)$, where $\text{Exp}(\mu)$ denotes an exponential random variable with mean μ . The random variable X with mean $\mu > 0$ is said to have the property of harmonic new worse than used in expectation (HNWUE) if $X \geq_{\text{icx}} \text{Exp}(\mu)$. Note that by known basic properties of the orders $\leq_{\text{icx}}$ and $\leq_{\text{dil}}$, it follows that the random variable X with mean $\mu > 0$ is HNBUE (HNWUE) if, and only if, $X \leq_{\text{dil}} [\geq_{\text{dil}}] \text{Exp}(\mu)$. The harmonic mean residual life order can be used to characterize the HNBUE and HNWUE notions as follows:

Theorem 23. *The random variable X with mean $\mu > 0$ is HNBUE [HNWUE] if, and only if, $X \leq_{\text{hmrl}} [\geq_{\text{hmrl}}] \text{Exp}(\mu)$.*

It is easy to verify that a nonnegative random variable X with mean $\mu > 0$ satisfies $X \leq_{\text{icx}} [\geq_{\text{icx}}] \text{Exp}(\mu)$ if, and only if, $A_X \leq_{\text{st}} [\geq_{\text{st}}] \text{Exp}(\mu)$. This observation yields the following characterization of the HNBUE and HNWUE concepts:

Theorem 24. *The nonnegative random variable X with a finite mean $\mu > 0$ is HNBUE [HNWUE] if, and only if, $A_X \leq_{\text{st}} [\geq_{\text{st}}] \text{Exp}(\mu)$.*

INTRODUCTION

Air traffic management (ATM) can be defined as the broad collection of services that support safe, efficient, and expeditious aircraft movement. It is common to distinguish two basic ATM components: air traffic control (ATC) and air traffic flow management (ATFM).

Air Traffic Control refers to processes that provide tactical separation services, that is, real-time separation procedures for collision detection and avoidance. ATC is usually performed by human controllers who watch over three-dimensional regions of airspace, called *sectors*, and dictate local movements of aircraft. Their aim is to maintain separation between aircraft while moving traffic as expeditiously as possible and presenting the traffic in an orderly and useful manner to the next sector. Each sector can only be occupied by a limited number of aircraft; the limit is determined by a controller's ability as well as the complexity of traffic patterns. As such, ATC actions are of a more tactical nature and primarily address immediate safety concerns of airborne flights.

Air Traffic Flow Management, on the other hand, refers to processes of a more strategic nature. ATFM procedures detect and resolve demand-capacity imbalances that

jeopardize safe separation. By keeping the workload of air traffic controllers to a manageable level, traffic flow management can be viewed as the first line of defense in maintaining system safety. Whereas ATC generally controls individual aircraft, ATFM usually adjusts aggregate traffic flows to match scarce capacity resources. Accordingly, ATFM actions have a greater potential to address system efficiency.

Air Traffic Flow Management Objectives and Challenges

The objective of ATFM is to mitigate imbalances between the demand for air traffic services and the capacity of the air transportation system, so as to ensure that aircraft can flow through the airspace *safely* and *efficiently*. In the long term, this implies efforts to prevent structural imbalances by reducing demand (by, for example, congestion pricing or auctioning off landing slots; see Ball *et al.* [1]) or increasing capacity (i.e., building new runways). In the short term, however, ATFM aims to limit—as much as possible—the impact of the congestion and delays that arise when the system is disrupted.

Fluctuating weather conditions, equipment outages, and demand surges all cause significant capacity–demand imbalances. Adverse weather conditions, in particular, frequently cause substantial reductions in airspace and airport capacity. Because these disruptions are highly unpredictable, ATFM will need to resolve the resulting capacity–demand imbalances in a dynamic manner. This is further complicated by the fact that airlines' flight schedules are highly interconnected. The aircraft, crews, and passengers that compose the flight schedule might all follow different itineraries, thus creating a complex interaction between an airline's flight legs. As a result, delays of a single flight leg can propagate throughout the network and local disruptions might have a global impact.

At the heart of the objectives and challenges of ATFM is the fact that

decision-making responsibilities are shared between a number of stakeholders. The actions performed by these stakeholders are highly interdependent, and therefore necessitate a significant degree of coordination. It is therefore no surprise that the coordination and cooperation between air traffic service providers and the airspace users have become increasingly important. In the United States, for instance, nearly all efforts to improve ATFM, nowadays, are guided by the so-called collaborative decision-making (CDM) philosophy.

The CDM philosophy recognizes that to implement appropriate ATFM actions, the service provider needs an accurate assessment of flight status and intent. Airspace users, on the other hand, need the flexibility to adjust their schedules, and can only provide accurate information if they know the actions planned by the provider. Given the relatively short response times, the real-time exchange of information between the service provider and users is therefore a critical component of ATFM functionality.

In addition, it has become increasingly clear that the service provider should not be solely responsible for determining the delays, reroutes, and so on, required to resolve congestion. While both the service provider and users can possibly delay or reroute flights, certain actions that can alleviate congestion are only available to airlines. In the United States, for example, only an airline can decide to cancel flights or to reassign passengers, crew, and aircraft. Consequently, the notion of CDM emphasizes that any successful attempt at flow management requires significant involvement from airlines and other users. Such decisions involve economic trade-offs that the air traffic service provider is not in a position to make.

Air Traffic Flow Management Initiatives

For the major portion of the previous century, the coordination of air traffic proceeded largely through tactical ATC procedures. In the United States, it was not until the aftermath of the air traffic controllers' strike of

1981 that the Federal Aviation Administration (FAA) first implemented a systematic form of flow management known as *ground holding*. Under ground holding, aircraft departures are restricted until it is determined that sufficient airspace is available for the aircraft. Initially, the use of ground holding was primarily instituted to reduce workload for the inexperienced controllers that were hired in the wake of the mass firings that accompanied the strike. However, the continued growth in air traffic that followed the airline deregulation act of 1978, together with changes in traffic patterns such as the "hub and spoke" scheduling practices used by airlines, have gradually increased the scope of ATFM initiatives.

To implement these initiatives, traffic management has a variety of control techniques at their disposal. These control techniques can be organized as follows:

- ground holding controls, that is, the selective assignment of delays to flights prior to their departure;
- rerouting controls, which impose constraints on the flight paths that an aircraft can fly; and
- airborne holding controls, which result in flight delays after take-off. Airborne delays can be applied using a variety of methods, ranging from *spacing* to *speed controls* and *vectoring*. Spacing, between aircraft traveling in the same direction, specifies and controls the separation between successive aircraft. Speed control aims to ensure safe and efficient flow of aircraft by selectively increasing or decreasing their speed, while vectoring, corresponds to minor spatial deviations from flight path.

Generally speaking, ground holding and rerouting techniques are used to support strategic activities, in that they are applied proactively hours in advance. Airborne holding controls, with the exception of spacing, are commonly used for tactical flow management and are initiated reactively. It is important to note, however, that the use of these proactive controls is perhaps uniquely relevant to air transportation: in contrast to

most other forms of transportation, aircraft cannot be stopped en route and therefore ATFM cannot allow traffic jams to develop.

MODELS FOR AIR TRAFFIC FLOW MANAGEMENT

The explosive growth and ensuing congestion in air traffic has motivated a considerable amount of research that considers the application of operations research models to ATFM. The use of decision models to support ATFM received relatively little attention prior to the 1980s, and most of the literature dates to after the emergence of formal flow management procedures that followed the air traffic controllers' strike in 1981.

This section provides an overview of the principal operations research models that have been proposed in support of ATFM. We note that, due to space limitations, our emphasis is on optimization models; for a review that also includes the more descriptive simulation or queueing models that have been used in ATFM, we refer the reader to the surveys [2,3]. Here, we distinguish between airport allocation models, where an airport represents the single constrained resource, and airspace allocation models, where congestion occurs throughout a network of airports and/or sectors of airspace.

Airport Allocation

Without a doubt, the prototypical application of optimization models for ATFM is in the so-called ground holding problem (GHP). GHP was first introduced by Odoni [4] and by Andreatta and Romanin-Jacur [5], and assumes that only a single airport in the system faces a reduction in capacity for some period of time. As a result, the flights that are scheduled to arrive during this time period will have to be delayed: due to both safety and economic concerns, this is typically done by delaying flights prior to their departure. A central concern in this setting is that the problem of assigning ground delays is both stochastic, because capacity forecasts have a significant degree of uncertainty, and dynamic, because the forecasts are updated frequently and provide new information on

how the weather conditions at an airport are changing. Thus, the overall goal of the GHP is to balance the risk of excessive ground delays (which can lead to underutilization of the airport) with the risk of excessive airborne delays (which can lead to dangerous levels of airborne holding).

Richetta and Odoni [6] were the first to propose an integer programming model to solve a multiperiod stochastic GHP. In their model, uncertainty in airport capacity is represented by a finite set of scenarios, each of which represents a time-varying profile of the airport capacity that is likely to occur. The goal is to assign ground delays to flights, given uncertainty in airport capacity, in order to minimize the total expected delay cost. The model formulation is given below.

As in most of the discrete optimization models for ATFM, the planning horizon is divided into equal time periods. Let there be Q capacity scenarios, each scenario depicting a possible evolution of airport arrival capacity over the planning period with the scenario $q \in \{1, \dots, Q\}$ having a probability of occurrence equal to p_q . Let M_t^q denote the capacity at time period t under the scenario q . In order to ensure that all flights that are scheduled to land get assigned a landing slot during a time period, let there be a time period $T + 1$ with unlimited capacity under all scenarios. In their model, Richetta and Odoni classified the flights that are scheduled to arrive during each time period into K cost classes. Let N_{kt} denote the number of flights, belonging to cost category k , that are scheduled to arrive at the airport during the time period $t \in 1, \dots, T$. The cost of ground holding a flight of class k for i time units is denoted by the cost function $G(k, i)$. As illustrated below, this cost function allows us to capture nonlinear ground delay costs for flights, while keeping the objective function linear in decision variables. Let C_a denote the unit cost of airborne holding for all flights.

The decision variables are denoted by X_{ktj}^q , which indicate the number of flights in class k scheduled to arrive during time period t that are reassigned to arrive during time period j under capacity scenario q . Let W_t^q denote the number of aircraft that are unable to land during time period t under scenario q ,

and hence face airborne holding during that time period. The objective function minimizes the total expected cost of ground and airborne delays. The integer program is given as follows:

$$\begin{aligned} \text{Min} \quad & \sum_{k=1}^K \sum_{t=1}^T \sum_{j=t}^{T+1} C_g(k, j-t) X_{ktj} \\ & + C_a \left\{ \sum_{q=1}^Q p_q \sum_{t=1}^T W_t^q \right\} \end{aligned} \quad (1)$$

subject to

$$\begin{aligned} \sum_{j=t}^{T+1} X_{ktj} &= N_{kt}, \quad k = 1, \dots, K; \\ t &= 1, \dots, T \end{aligned} \quad (2)$$

$$\begin{aligned} \sum_{k=1}^K \sum_{j=1}^t X_{kjt} + W_{t-1}^q - W_t^q &\leq M_t^q, \\ q &= 1, \dots, Q; \quad t = 1, \dots, T+1 \end{aligned} \quad (3)$$

$$W_0^q = W_{T+1}^q = 0, \quad \forall q = 1, \dots, Q \quad (4)$$

$$\begin{aligned} X_{ktj} &\geq 0 \quad \text{and integer}, \quad k = 1, \dots, K; \\ t &= 1, \dots, T; j = 1, \dots, T+1 \end{aligned} \quad (5)$$

$$\begin{aligned} W_t^q &\geq 0 \quad \text{and integer}, \quad t = 1, \dots, T; \\ q &= 1, \dots, Q. \end{aligned} \quad (6)$$

Constraint set (2) ensures that all flights scheduled to arrive during any time period get rescheduled to land before the end of planning horizon. Constraint set (3) imposes an upper bound on the number of aircraft that can land during a time period under different scenarios. Kotnyek and Richetta [7] showed that the constraint matrix of the above formulation is not totally unimodular, and in some cases the LP relaxation to the above IP will not yield integer solutions. However, if all flights belong to only one cost category, and if the ground delay cost function is monotonically increasing, the Richetta–Odoni model guarantees integer solutions (see Kotnyek and Richetta [7] for details).

It is important to note that formulation described above presents a *static* model, in that the model does not incorporate the recourse options that may be available at the start of each decision epoch. While this

model can be implemented in a dynamic manner, by repeatedly solving the model in each decision epoch (and executing the first stage), other approaches have aimed to explicitly incorporate the dynamic nature of the problem. In particular, Richetta and Odoni [8] were also the first to develop a multistage stochastic integer program with recourse for the GHP. Such a model not only accounts for uncertainty, but also utilizes updated information on capacity changes in the decision-making process, thus explicitly accounting for GHP dynamics. As in the static models, uncertainty in airport capacity is represented by a finite set of scenarios. These scenarios are arranged in a scenario tree, which reveals the availability of information on airport operating conditions (see Fig. 1 for an example). The information is based on forecasts, so that capacity changes are anticipated before they occur. If branching points in the scenario tree occur only when the operating conditions change physically (for example, at possible fog burn-off times) the active branch of the scenario tree will reflect the actual capacity at any instant. In the Richetta–Odoni model, flights are assigned ground delays as their departure time approaches, so that the decisions can be made with the most up-to-date information. Once assigned, however, ground delays cannot be revised, even though this is technically possible so long as the flight has not yet departed. On the one hand, this results in less efficient solutions as there might be unnecessary ground delays that can be recovered by appropriate revision, while on the other hand it results in a higher degree of predictability of flight departure times. Mukherjee and Hansen [9,10] extended the multistage stochastic IP formulation of Richetta and Odoni, and proposed a dynamic model for the GHP that can revise ground delays of flights in response to updated information on airport capacity. Their formulation is discussed below (wherever possible, we use the same notation as in the static model presented above).

Let Φ be a set of flights that are scheduled to fly to an airport for which a ground-holding program is necessary. As in the static model, the time of day is divided into a finite set

Figure 1. Scenario tree of evolving airport arrival capacity.

of time periods of equal duration. The scheduled departure and arrival times of a flight f are denoted by d_f and a_f respectively. The scenario tree is input to the model through the following variables. Let B ($B \geq Q$) be the total number of branches in the scenario tree. Each branch corresponds to a set of scenarios. The scenarios corresponding to branch $b \in \{1, \dots, B\}$ are given by the set $\Omega_b = \{S_1^b, \dots, S_k^b, \dots, S_{\pi_b}^b\}; S_k^b \in \{1, \dots, Q\}$. We assume that each branch has start and end nodes corresponding to the beginning of time periods. The time periods corresponding to the start and end nodes of branch b are denoted by o_b and μ_b , $b \in \{1, \dots, B\}$. The decision variables in the model are binary variables defined as follows:

$$X_{ft}^q = \begin{cases} 1, & \text{if flight } f \text{ is planned to arrive} \\ & \text{during time period } t \text{ under} \\ & \text{scenario } q; \text{ and} \\ 0, & \text{otherwise.} \end{cases}$$

Corresponding to the X_{ft}^q is a set of corresponding auxiliary variables for the departure time period. Specifically we define

$$Y_{ft}^q = \begin{cases} 1, & \text{if flight } f \text{ is released for} \\ & \text{departure during time period} \\ & t \text{ under scenario } q; \text{ and} \\ 0, & \text{otherwise.} \end{cases}$$

The departure release variables track the planned arrival times but are displaced earlier in time by the amount $a_f - d_f$. Hence the variables Y_{ft}^q are related to X_{ft}^q as follows:

$$Y_{ft}^q = X_{f, t+a_f-d_f}^q \quad \in \{d_f..T\}, q \in \{1, \dots, Q\}. \quad (7)$$

The objective function and the set of constraints are given as follows:

$$\text{Min } \sum_{q=1}^Q p_q \left\{ \sum_{f \in \Phi} \sum_{t=a_f}^{T+1} (t - a_f) X_{ft}^q + \sum_{t=1}^T \lambda W_t^q \right\} \quad (8)$$

subject to

$$\sum_{t=a_f}^{T+1} X_{ft}^q = 1, \quad f \in \Phi, q \in \{1, \dots, Q\} \quad (9)$$

$$W_{t-1}^q - W_t^q + \sum_{f \in \Phi: a_f \leq t} X_{ft}^q \leq M_t^q, \quad t \in \{1, \dots, T+1\};$$

$$q \in \{1, \dots, Q\}; \quad (W_0^q = W_{T+1}^q = 0) \quad (10)$$

$$Y_{ft}^{S_1^b} = \dots = Y_{ft}^{S_k^b} = \dots = Y_{ft}^{S_{\pi_b}^b}; f \in \Phi, \\ t \in \{1, \dots, T\}; S_k^b \in \Omega_b: \pi_b \geq 2, o_b \leq t \leq \mu_b \quad (11)$$

$$X_{ft}^q, Y_{ft}^q \in \{0, 1\}; W_t^q \geq 0 \quad \text{and integer} \\ f \in \Phi, q \in \{1, \dots, Q\}, t \in \{1, \dots, T\}. \quad (12)$$

Constraint set (9) implies that all flights are planned to arrive by the end of planning horizon $T + 1$. Constraint set (10), which is similar to Equation (3) in the static model presented above, ensures that the number of arrivals during any time period is limited by the scenario-specific airport arrival capacity for that time period. The number of arrivals in a time period t is the sum of the reduction in the size of the arrival queue between the end of t and the end of the previous time period $t - 1$, and the number of flights whose planned arrival time is in t . If the number of planned arrivals during a time period exceeds the arrival capacity, then the excess flights are subject to airborne delay and added to the arrival demand for the next time period. Constraint set (11) is a set of coupling constraints, sometimes known as *nonanticipatory constraints* in the literature [11], on the ground holding decision variables. These constraints force ground delay decisions to be made solely on information available at time t . For a given time period t , it is required that the ground holding decisions are the same for all scenarios associated with the same scenario tree branch b (in other words the scenarios belonging to the set Ω_b) in that time period.

Variants and Extensions. The static and dynamic stochastic models outlined above illustrate the fundamental decisions and trade-offs that arise in the GHP. Nevertheless, there are also a number of additional concerns, which have been addressed in several variants of the GHP.

Most of the optimization models for the GHP, for example, address only the arrival capacity shortfall at an airport, and decide on the amount of ground delay to impose on various incoming flights. Gilbo [12,13], however, presented optimization models to assign ground delays to both arrival and departure traffic at an airport. His model not only solves for ground delays of aircraft, but also optimal allocation of airport capacity to arrival and departure operations. Another stream of research [14–16] has a more tactical perspective, and considers the optimal sequencing of aircraft landings while taking into account the (flight-pair dependent)

separation standards that are required in the wake turbulence that is generated.

With the emergence of the CDM paradigm, fairness issues related to the distribution of delays in the GHP have also received attention. Under CDM, a three-step process is used to allocate airport capacities during ground delay programs (GDPs). First, airport arrival slots are assigned to airlines in a first-scheduled, first-served manner, using the ration-by-schedule (RBS) procedure. Subsequently, a substitution process allows airlines to adjust their part of the schedules according to their internal objectives. Finally, a reallocation process called *compression* aims to ensure maximum utilization when flights have been canceled or delayed [17]. In such a setting, the GHP has to determine the aggregate number of slots that are made available in each period; subsequently, these slots can be allocated using the RBS procedure. Ball *et al.* [18] address this in a model for the static stochastic GHP, and show that the resulting integer programming formulation has a dual network structure and thus can be solved efficiently. In practice, flow managers often address risk by exempting long-haul flights. This, however, raises equity issues. Vossen *et al.* [19] show that exemptions can result in a systematic bias toward airlines operating long-haul flights, and present an optimization model to mitigate those biases that can be used within a CDM framework. Hoffman *et al.* [20] also proposed an algorithm, which they termed as *equitable ration-by-distance*, which performs better, with respect to both equity and efficiency, than the distance-based flight exemptions currently used in practice by the FAA when implementing a GDP.

Finally, scenario and scenario tree generation present a vital issue in application of multistage stochastic optimization problems. While scenario generation has mostly been studied in the context of stochastic programming problems in finance, Liu [21] has recently applied statistical clustering techniques to develop capacity scenarios and scenario trees for the stochastic single airport ground holding problem (SAGHP) from historical airport capacity data. More generally, one of the primary shortcomings

of the scenario-based models for SAGHP is that they assume that a limited number of capacity profiles can occur. However, in reality the set of possible scenarios can change with time. Furthermore, scenario-based models impose a decision tree structure when in reality improved information about future capacity can be obtained continually rather than at discrete branching points. In light of these shortcomings, Liu and Hansen [22] proposed a “scenario-free” sequential decision making model, based on dynamic programming techniques, for the stochastic SAGHP. To reduce the computational complexity associated with large-scale problems, they proposed several prioritization-based heuristics.

Airspace Allocation

Optimization models and algorithms that address en route capacity constraints treat the airspace system as a multiple origin–destination network along which traffic flow must be assigned. As such, these models often incorporate the network effects (or delay propagation) of arrival delays of flights that are not considered in the GHP.

Deterministic optimization models addressing en route capacity constraints were first formulated as a multicommodity network-flow problem by Helme [23]. These models deal with aggregate flows instead of individual flights, and aim to determine an optimal assignment of ground and airborne delays in an air transportation network; that is, rerouting decisions are not considered. Disaggregate deterministic 0-1 integer programming models for deciding ground and airborne holding of individual flights when faced with airport and airspace capacity constraints were formulated by Lindsay *et al.* [24]. The proposed model, which was named the *Time Assignment Model* (TAM), decides on the temporal and spatial location of each aircraft, given a set of capacity constraints on national airspace system (NAS) resources. The input parameters are the origin and destination airports, a set of en route fixes each aircraft must fly over, as well as the time-varying capacity profile of each of these airspace elements. More recently, Bertsimas and Stock Patterson [25]

presented a deterministic 0-1 IP model to solve a similar problem. For each aircraft, a predetermined set of en route sectors is specified as the route between its origin and destination. The model decides on the departure time and sector occupancy time of each aircraft. Bertsimas and Stock-Patterson showed that their formulation is NP-hard. In many practical cases however the LP relaxation of their IP yields integer optimal solutions, and hence their model is considered to be computationally efficient in practice. The Bertsimas–Patterson model can be summarized as follows.

Let K denote a set of airports and F be the set of flights scheduled between those airports, and let J denote the set of en route sectors. Let Ψ denote the set of pairs of flights that are continued, that is, $\Psi := \{(f, f') : f' \text{ is continued by } f\}$. Let the planning horizon be divided into T time intervals of equal duration. For a given flight f , let N_f denote the number of resources (i.e., sectors and airports), and $P(f, i)$, $1 \leq i \leq N_f$, denote the i th resource along flight f 's path. Note that $P(f, 1)$ and $P(f, N_f)$ represent the departure and arrival airports respectively. Depending on the trajectory, each flight is required to spend a minimum number of time units, l_{fj} , in a sector j that lies along its flight path. Let the capacity of resources during a time interval t be denoted as follows: $D_k(t)$ equals the departure capacity of airport $k \in K$, $A_k(t)$ the arrival capacity of k , and $S_j(t)$ the sector capacity (i.e., the number of aircraft allowed to be present) in sector $j \in J$. The flight-specific scheduled times and delay costs are denoted as follows: d_f , a_f , and s_f are the scheduled departure, arrival, and turnaround times (the minimum ground time for an aircraft between flights) respectively, while c_f^g and c_f^a denote the unit costs of delaying a flight on the ground and in the air.

The binary decision variables, which are nondecreasing, are defined as follows:

$$X_{ft}^j = \begin{cases} 1, & \text{if flight } f \text{ arrives at sector } j \text{ by} \\ & \text{time } t; \text{ and} \\ 0, & \text{otherwise.} \end{cases}$$

To reduce the size of the formulation, Bertsimas and Patterson define a feasible time

window for each flight that establishes when that flight can occupy a resource along its flight path. The feasible time periods, for a flight f to be present in sector j , are represented by a set $T_f^j, j \in P(f), 1 \leq i \leq N_f$. On the basis the decision variables, the total ground and airborne delays of a flight are given by the following expressions:

$$g_f = \sum_{t \in T_f^k, k=P(f,1)} t(w_{ft}^k - w_{f,t-1}^k) - d_f; \text{ and}$$

$$r_f = \sum_{t \in T_f^k, k=P(f,N_f)} t(w_{ft}^k - w_{f,t-1}^k) - a_f - g_f.$$

The objective function and the set of constraints are defined as follows:

$$\text{Min} \sum_{f \in F} (c_f^g g_f + c_f^a r_f)$$

subject to

$$\sum_{f: P(f,1)=k} (w_{ft}^k - w_{f,t-1}^k) \leq D_k(t) \quad \forall k \in K, t \in \{1, \dots, T\} \quad (13)$$

$$\sum_{f: P(f,N_f)=k} (w_{ft}^k - w_{f,t-1}^k) \leq A_k(t) \quad \forall k \in K, t \in \{1, \dots, T\} \quad (14)$$

$$\sum_{f: P(f,i)=j, P(f,i+1)=j'} (w_{ft}^j - w_{f,t-1}^{j'}) \leq S_j(t) \quad \forall j \in J, t \in \{1, \dots, T\} \quad (15)$$

$$w_{f,t+l_{fj}}^{j'} - w_{ft}^j \leq 0 \quad \begin{cases} f \in F, t \in T_f^j, j = P(f,i), \\ j' = P(f,i+1), i < N_f \end{cases} \quad (16)$$

$$w_{ft}^k - w_{f',t-s_{f'}}^k \leq 0 \quad \begin{cases} (f',f) \in \Psi, t \in T_{f'}^k, \\ k = P(f,1) = P(f',N_{f'}) \end{cases} \quad (17)$$

$$w_{ft}^j - w_{f,t-1}^j \geq 0 \quad \begin{cases} \forall f \in F, j \in P(f,i), \\ 1 \leq i \leq N_f, t \in T_f^j \end{cases} \quad (18)$$

$$w_{ft}^j \in \{0, 1\} \quad \forall f \in F, j \in J, t \in \{1, \dots, T\}. \quad (19)$$

The objective function minimizes the total cost of flight delays. The set of constraints are classified into two categories: capacity constraints (13–15) and connectivity constraints

(16–18). The capacity constraints ensure that the flow is bounded by the capacities of each resource in the system—airports and sectors. For example, constraint set (15) ensures that the total number of flights within a sector during any time interval does not exceed the sector capacity during that time period. Within the connectivity constraints, there are two subcategories: sector and flight connectivity. The sector connectivity constraints (16) ensure that each flight passes through the proper sequence of sectors in its route between origin and destination airports. The flight connectivity constraints (17) ensure that an aircraft must spend a minimum “turnaround” time at an airport before it can depart on its subsequent leg. Constraint set (18) ensures that the decision variables are nondecreasing, while Equation (19) ensures that they are binary.

Variants and Extensions. The Bertsimas–Patterson formulation allows several important variants and extensions. If sector capacity constraints are removed, for example, the formulation corresponds to a multiairport ground holding problem (MAGHP). MAGHPs [26–28] consider a network of airports and optimize the ground delay assignment to various flights, so that delay on a given flight segment can propagate to downstream segments flown by the same aircraft. At the same time, multiple connections at a hub airport can also be addressed in the Bertsimas–Stock formulation by modifying flight connectivity constraints, while interdependence between arrival and departure capacity constraints can be captured using a notion of capacity envelopes. Another interesting alternative is proposed by Lulli and Odoni [29], who introduce a more macroscopic version of the Bertsimas–Stock formulation that omits some of its details (i.e., speed control, en route airborne holding). Lulli and Odoni argue that the resulting model is particularly appropriate for ATFM in Europe, where congestion on en route sectors is common and much more prevalent than in the United States. Using their model, the authors show that fundamental conflicts may arise between efficiency and equity, and

illustrate the potential benefits of selective airborne delay assignments.

In addition, the incorporation of rerouting decisions presents another important research direction. Bertsimas and Patterson present a more aggregate model (similar to the approach by Helme [23]) that addresses routing as well as ground and airborne holding decisions. Their model is formulated as a dynamic, multicommodity, integer network-flow problem with certain side constraints. Aggregate flows are generated by solving a Lagrangian relaxation of the LP, in which the capacity constraints are relaxed into the objective function. Subsequently, a randomized rounding heuristic is applied to decompose the aggregate flows into a collection of individual flight paths. Finally an integer packing problem is solved to obtain feasible, and near-optimal, flight routes. Another important alternative is proposed by Bertsimas *et al.* [30], who extend the Bertsimas–Patterson formulation by allowing for rerouting decisions. Specifically, they propose a formulation where reroute options are represented using a compact set of additional constraints. Their experiments indicate that the resulting models can be solved efficiently for realistic large-scale problem instances. At a more microscopic level, routing decisions have also been considered by Sherali *et al.* [31,32]; their models consider smaller regions of airspace, but incorporate more detailed representation of flight trajectories and sector capacities.

Applying the Bertsimas–Patterson model for large-scale problems in ATM can pose serious computational challenges. Several variants of the model that address these computational issues have also been proposed in the literature. Rios [33] applied the Dantzig–Wolfe decomposition technique to solve the Bertsimas model. Such decomposition techniques are particularly beneficial when the subproblems are solved simultaneously in multiple processors. In another study [34], the decision variables were limited to assigning flight departure times only. No airborne holding was allowed. Airborne holding, and subsequent rerouting was invoked when aircraft approached weather-impacted regions. Thus the model proposed

by Grabbe *et al.* [34] accounts for uncertainty in weather forecast by delaying the rerouting and airborne holding decisions until further in time when precise information becomes available. Several other recent papers [35,36], also discuss stochastic models for airspace capacity allocation, and we expect this to be a fertile area for future research.

Finally, we also note the so-called Eulerian models [37–39] that have been proposed for ATFM. These models spatially aggregate air traffic count to generate models for air traffic flow in one-dimensional control volumes. The complexity of aggregate models depends on the number of such control volumes, which is typically much less than the total aircraft count. A linear, dynamic systems model, proposed in Sridhar *et al.* [39], was developed using the number of departures from various centers, and by estimating the flows between adjacent centers using historical air traffic data. Subsequently, an Eulerian–Lagrangian model based on multicommodity network flow was developed based on historical traffic data [40]. The Eulerian flow model is similar to that in Sridhar *et al.* [39]. The problem of controlling flow was posed as an IP in which the dynamic flow model represents the set of constraints.

CHALLENGES AND RESEARCH DIRECTIONS

While the current body of research in ATFM is certainly large and varied, it is nevertheless important to note that operations research models have generally not seen a widespread adoption within ATFM practice. Whereas the field of operations research has had a critical impact within other areas of the airline industry (e.g., revenue management, airline schedule planning, and crew rostering), its applications to flow management have been more isolated and, generally speaking, of a more limited scope. It is important to note, however, that the context in which ATFM operates makes it difficult to adopt operation research models on a large scale. Because ATFM is concerned with safety and day-to-day operations, the environment will naturally be more conservative and slower to adopt new models than a

for-profit business operating in a competitive environment. In a system this complex, an incremental and evolutionary approach to adopting new technologies has long been preferred. At the same time, it should also be noted that the models' intensive data requirements together with sometimes restrictive assumptions also complicates the implementation of optimization models in practice. The large body of work on stochastic GHPs, for instance, generally uses a scenario tree as an input. The development of appropriate decision trees, however, presents a formidable task in and by itself, and has received attention only recently [41,42]. Moreover, the model's intended users might find it hard to determine appropriate values for models parameters that—while mathematically convenient—do not correspond well with the manner in which they make their decisions. Models for the GHP have traditionally used parameters to represent the relative “cost” of ground and airborne holding. It can be difficult for the service provider to determine values for such parameters, or understand how varying these parameters will impact results. Thus, even though we believe the research on ATFM has made significant progress and yielded important new ideas, it is safe to say that the field as a whole is still in its early stages.

As such, we believe that there is a clear need and opportunity for further ATFM research. Over the next two decades, the demand for air traffic in the United States is expected to grow to two or three times its current level [43]. Given that the air transportation system can barely manage current demand levels, stakeholders in the system are actively pursuing ways to accommodate this future growth. These developments are wide-ranging, and—in the United States—are organized in an integrated plan that is known as the *Next Generation Air Transportation System (NextGen)*. The NextGen concept envisions a fundamental departure from the current approach to air transportation operations that provides a common framework for safety, efficiency, security, and environmental concerns. And, while the NextGen vision will undoubtedly undergo changes and revisions in the years to

come, we believe that its key capabilities and fundamental characteristics offer numerous opportunities for operations research analyses and modeling.

One important aspect of these models will be the ability to account for user behavior and response. A potential area of research in this area is the application of market-based mechanisms, both in the medium and short term, for managing the air transportation system's resources. In the medium-term, for instance, airlines could bid for and own a certain proportion of system resources. Subsequently, they might be able to trade the resources they own with other users on a daily basis. Such an approach would require users to develop models that value their resources, and support decisions related to resource trading on a secondary market. The service provider, on the other hand, would have to design this “marketplace,” and provide a platform for resource trading. Examples of initial research in this area include the use of auctions to assign airport arrival slots [1] and the use of slot trading during GDPs [44].

In addition, the use of new models for disruption management also offers several possibilities. Given that most disruptions are due to bad weather conditions, further development related to the above-mentioned decision models that integrate uncertainty forms one important research direction in this area. Another promising area is the development of decision support models that will facilitate contingency planning, to increase responsiveness under changing conditions. Such a framework also needs corresponding models at the user side, to allow for fully integrated airline recovery methods that can evaluate and establish user preferences under the various potential scenarios.

AIRLINE RESOURCE SCHEDULING

AMY COHN

Engineering, University of
Michigan, Ann Arbor,
Michigan

INTRODUCTION

Passenger aviation is critical to today's society, with passengers relying on airlines (carriers) to provide safe, reliable, and affordable travel for both business and leisure. In 2009, more than 9.9 million flights originated and/or terminated in the United States alone, carrying more than 764 million passengers [1]. Every one of these flights required the coordinated utilization of many shared resources including aircraft, crews (cockpit, cabin, and ground), taxiways and runways, the airspace, and more. In some cases, resources are shared across multiple flights within a single company (e.g., aircraft, crews) while other resources (such as runways and the airspace) must be shared across airlines, adding further complexity. This sharing of resources, along with the associated underlying network structure of an airline, results in significant coordination challenges.

The operations research (OR) community has long played an active role in virtually all aspects of the airline industry, helping to plan, schedule, coordinate, and operate it. In the past decade, this role has been particularly important. Major challenges such as SARS, the US terrorist attacks of 9/11, the 2008 spikes in fuel prices, and a global economic downturn have made it increasingly important that airlines utilize resources efficiently. To accommodate, the OR community has expanded its focus to include topics such as robust planning, integrated planning, and enhanced recovery techniques.

In the process of solving these challenging airline problems, the OR community has also made broader contributions. Specifically, several of the modeling and algorithmic techniques developed to solve airline planning problems have applicability to a broad class of other application areas as well.

This article therefore has two purposes. The first is to introduce readers new to the field of airline OR to the problems that have been solved and the problems currently under investigation, and to provide initial references to some of the key literature. The second is to review some of the key modeling and algorithmic contributions, which have relevance in many other fields beyond aviation.

OPERATIONS RESEARCH PROBLEMS IN THE AIRLINE INDUSTRY

Within passenger aviation, there is a vast array of complex decisions to be made, ranging from aircraft design and airport construction to the control of the airspace to airline planning and scheduling. Similarly, there is a wide range of decision makers, including carriers, government regulators, airport authorities, and passengers. We focus here on resource scheduling from the perspective of the carriers. Resource scheduling problems range in timescale from years, such as the decision to purchase an aircraft, to minutes, such as deciding how to reaccommodate passengers who have missed their connections. These problems cover many different resources including aircraft, pilots, flight attendants, gates, baggage, maintenance workers and facilities, and, of course, passengers. In addition, they must all address underlying uncertainty, including variability in demand, inclement weather, and unexpected maintenance issues. Furthermore, these problems must all address the system complexity associated with the underlying network structure of airline systems and the sharing of a finite set of resources.

Within the set of carrier resource scheduling problems, we focus primarily on the established literature in *fleet assignment*, *crew scheduling*, and *aircraft routing*, as well as the emerging literature on integrated planning and robust planning. We also briefly touch upon important future areas of research. Before doing so, we first briefly highlight some important areas of airline OR. These references are not intended to be an exhaustive survey, but rather to give a sense of the wide range of work that has been done and some initial sources for the interested reader.

Schedule generation

Airlines work on the *schedule generation* process a year or more in advance of the day of operation, predicting the demand for flights between origin–destination (O–D) pairs and subsequently deciding which flights to offer and with what frequency, as well as how to partner with other airlines through code-sharing and partnering agreements. Gopalan and Talluri [2] provide a survey paper identifying various schedule generation strategies. Early work by Daskin and Panayotopoulos [3] provides a Lagrangian relaxation to solve the assignment of aircraft to routes. Warburg *et al.* [4] and Jiang and Barnhart [5] provide a dynamic scheduling model that uses changes in the fleet assignment and minor flight retimings to update the schedule as booking data becomes available.

Revenue management, pricing, and passenger flow models

Revenue management and *pricing* problems focus on strategies to maximize profits from ticket sales. This is an evolving field of study, especially as new purchasing channels and new information systems become available. Related work can be found in McGill van Ryzin [6], Talluri and van Ryzin [7], Belobaba *et al.* [8], Fiig *et al.* [9], Lardeux [10]. Acting as a bridge between revenue management and fleet assignment, passenger flow

modeling [11] finds an optimal (i.e., revenue-maximizing) selection from a set of candidate itineraries given a fixed set of flight capacities. This solution, idealized in the sense that it assumes that an airline has complete control over which itineraries are purchased, provides a bound on the revenue that can be generated from a given fleet schedule. More recently, Dumas and Soumis [12] have incorporated uncertain demand and spill estimates within passenger flow modeling.

Demand driven dispatch and dynamic fleet

Even though airline plans are set far in the future, they are subject to uncertainty until the day of operations. Early work by Berge and Hopperstad [13] suggests that airlines can benefit by dynamically adjusting their fleet assignment to better match aircraft capacity to passenger demand when updated information about passenger bookings is obtained. For a more recent discussion of this topic, see Shebalov [14] and Tekiner *et al.* [15]. As an extension to demand driven dispatch, two recent articles by Warburg *et al.* [4] and Jiang and Barnhart [5] explore the idea of not only modifying the fleet assignment but also slightly altering the flight schedule itself to increase the revenue in response to evolving information about passenger demand.

Recovery

Airline plans are rarely, if ever, executed as designed. Unexpected disruptions such as inclement weather and unplanned maintenance issues often lead to flight delays. The inherent underlying network structure is such that these delays can further propagate to cause other delays (e.g., a down-stream flight delayed owing to the delay of its incoming aircraft). The *recovery* problem focuses on how to quickly return to the original plan, re-accommodating passengers, crews, aircraft, and more, often through the use

of heuristics and rules-of-thumb. On the other hand, resource planning problems focus more heavily on profit optimization and have greater flexibility in their computational solution time. Recent research in this important and challenging area includes the works of Eggenberg *et al.* [16], Abdelghany *et al.* [17–19], and Kohl *et al.* [20].

Airport operations

- *Gate assignment* The *gate assignment* problem determines which terminal gates are assigned to which inbound/outbound flights. The objectives that have been considered in the literature include minimizing walking distance for connecting passengers or minimizing the total number of missed passenger connections. Related work can be found in Mangoubi and Mathaisel [21], Bihr [22], Haghani and Chen [23], and Bolat [24] and a recent survey paper by Dorndorf *et al.* [25].
- *Boarding strategies* Boarding strategies vary among airlines. In most cases, the objective of a successful boarding strategy is to minimize the overall boarding time on a full aircraft. For an example of how OR is used in developing and analyzing boarding strategies, see van den Briel *et al.* [26].
- *Baggage handling* Although not as visible as passengers, baggage handling also presents many challenges for airline operations. Ensuring that baggage is transported from origin to destination, often with connections in between, presents an opportunity for OR contributions. For an example on this research, see Abdelghany *et al.* [27].
- *Check-in staffing* Scheduling of ground staff has also been of recent interest to the OR community. Stollatz [28] examines the operational workforce plan at check-in counters.

On-demand air transportation

In recent years, on-demand air transportation has begun to evolve as a new

business model for air travel. Constructing and evaluating the networks and operating practices of such companies yields many interesting OR problems. See Espinoza *et al.* [29,30] for two recent papers in this area.

Congestion pricing and slot auctions

Certain airports exhibit very high levels of congestion, often because of both very high demand for travel into and out of that area and also limited geographical opportunity for airport expansion. The volume of traffic at these airports can lead to significant congestion-based delays, which can in turn propagate throughout the aviation system. Congestion pricing [31] and slot auctions [32] are two examples of external influences on how airlines choose to generate their flight schedules. Both of these have benefited from OR tools for analysis and assessment of the impact of such approaches. For some recent work on this topic, we refer the reader to the thesis of Harsha [33].

Analysis of delays

The OR community has also conducted significant empirical and quantitative analysis on passenger airline performance. Examples of this include AhmadBeygi *et al.* [34], Stollatz [35], Baik and Trani [36], and Balakrishna *et al.* [37].

We close this section by noting some valuable textbooks focusing on the airline industry and airline decision making: [38–40].

RESOURCE SCHEDULING PROBLEMS IN PASSENGER AVIATION

Within passenger aviation, the three resource planning problems that have received the greatest attention from the OR community (and achieved the greatest successes) are *fleet assignment*, *aircraft routing*, and *crew scheduling*. As such, we focus our primary attention here.

Note that most airlines typically offer between one and four flight schedules per year. For example, they may offer a winter

Figure 1. Resource allocation solution approach.

schedule and a summer schedule. Within each schedule, there is usually a consistent pattern that repeats weekly, with many domestic flights repeating daily. Approximately six months to a year before a new schedule begins operations (varying by carrier), the solving of fleet assignment, aircraft routing, and crew scheduling typically begins, with the three problems solved in sequence. The general time-line of solving these airline resource allocation problems can be seen in Fig. 1. In this figure, the solid lines show initial flow of information, with output from one problem providing input for the next. The dashed lines illustrate a feedback loop, where information from a later problem is used to revise the solution to an earlier problem.

First, the fleet assignment problem is solved, in which each flight is assigned a specific aircraft type. The goal is to maximize the projected revenue minus the operating cost associated with the assignments, subject to *cover constraints* (every flight must have exactly one fleet type), *balance constraints* (for each fleet type, the flow into an airport must equal the flow out), and *count constraints* (you cannot use more aircraft of a given type than you have in your fleet). Note that this problem results in a partitioning of the flights by subfleet. We can then solve a separate (and independent) aircraft routing and crew scheduling problem for each fleet type.

The goal of the aircraft routing problem is to build *lines-of-flight*, that is, sequences of flights to be flown by individual aircraft (these lines-of-flight will subsequently be assigned to specific aircraft in the tail assignment problem). There are two primary concerns when establishing lines-of-flight.

The first is to meet strict *maintenance requirements* as required by the Federal Aviation Administration (FAA) (in the United States) or other governing bodies. In order to ensure that it is possible to meet these scheduled maintenance requirements, lines-of-flight are created that start and end at *maintenance stations* (airports that have the capability to perform routine maintenance) without exceeding maintenance limits. The second goal in building lines-of-flight is to establish *flight connections*, that is, to identify pairs of sequential flights that will share a common aircraft. This has benefits from both the revenue side (charging a premium on desirable itineraries for flight pairs that do not require passengers to change aircraft) and the crew scheduling side (identifying good opportunities to allow crew to remain with an aircraft over multiple flights, which reduces the propagation of delays).

Once the aircraft routing problem has been solved, the crew scheduling problem can be addressed. Like aircraft routing, a separate crew scheduling problem is solved for each aircraft type, since pilots are trained to fly a specific aircraft type. Aircraft routing and crew scheduling can largely be solved independently of one another, with the exception of *short connects*. These are pairs of flights with a *tight turn*, that is, very little time between the arrival of the first flight and the departure of the second. Thus, it is only possible for a crew to be assigned to both of these flights if the flights were assigned to a common aircraft in the aircraft routing solution. In addition, because it is desirable to keep a crew with the same aircraft, the aircraft routing problem acts as a key input to the crew scheduling problem.

Similar to the aircraft routing problem, in which sequences of flights are constructed to be flown by a common aircraft, the main component of crew scheduling, the *crew pairing* problem, builds sequences of flights (*pairings*) to be flown by an individual crew (the specific crews are then matched to the pairings in a *crew rostering* or *bidline* problem). A pairing is a multiday sequence of flights that are not only sequential in space and time but also comply with all federally mandated rest requirements and duty limitations. The goal of the crew pairing problem is to construct the least-cost set of pairings such that all flights are covered exactly once.

Observe that there is significant interdependence between all of these problems. In particular, the fleet assignment substantially impacts the feasible regions for the aircraft routing and crew scheduling problems by partitioning the flights into independent sets. As such, this raises the question of whether higher quality solutions could be found by solving the three problems simultaneously. In fact, there is such benefit, but it comes at the cost of substantially increased computational challenges. A sequential approach has been used in the past, primarily for reasons of tractability. In contrast, a sequential approach may not only lead to suboptimal solutions, but can in fact result in infeasibility. As a result, carriers typically perform multiple sequential iterations with feedback between the three problems.

Once these three problems have been solved to satisfaction, typically months before the schedule's start date, the shorter term problems of tail assignment and crew rostering are conducted—typically on a repeated, rolling horizon throughout the duration of the schedule.

Finally, fleeting, routing, and crew scheduling decisions all continue to be made even at the operational level, when recovery decisions must be made in response to disruptions. In these cases, the problem constraints are largely the same, but the goals are often quite different (for example, instead of focusing on optimizing profits, the goal may be to return to the planned schedule

as quickly as possible) and the permissible run time to find solutions is much tighter, leading to a focus on fast-running heuristics and rules-of-thumb over optimization-based approaches.

FLEET ASSIGNMENT

Time-Space Networks

In the fleet assignment problem (FAM), we want to assign an aircraft fleet type to each flight in the schedule. The goal is to maximize profits subject to the cover, balance, and count constraints described in the section titled “Basic Fleet Assignment Model (FAM).” Before presenting formulations for this problem, we introduce the notion of *time-space networks* [41]. In a time-space network, each node in the network represents a physical location along with a specific moment in time. The arc connecting two nodes in such a network then represents a transition in both space and time. Such networks can be very powerful in a variety of applications, including but not limited to passenger aviation resource planning [42].

In airline planning problems, we often make use of a time-space network in which we have a *time-line* for each station (i.e., airport). A node on this time-line indicates a *flight event* at that station, that is, either an arrival or departure. Each flight then has two nodes, one on the time-line of its origin airport, at the time of its departure, and one at its destination airport, at the time of its arrival. We refer to the arc connecting these two nodes as a *flight arc*. In addition, we create a *ground arc* from each node on a time-line to the next node in time on that same time-line. These arcs represent aircraft remaining at the station in between the flight events. Figure 2 represents such a time-space network for two stations and two flights.

Basic Fleet Assignment Model (FAM)

Given the concept of a time-space flight network, we now present an integer programming (*IP*) formulation for FAM, as originally formulated by Hane *et al.* [41] and Jacobs *et al.* [43].

Figure 2. Example of a time-space network.

Sets

- F the set fleet types.
- L the set of flight legs.
- T the set of nodes, that is, flight events.
- S the set of stations.

Parameters

- c_{lf} the profit gained when leg l is assigned to fleet type f , $\forall l \in L, \forall f \in F$.
- N_f the number of aircraft of type f in the fleet, $\forall f \in F$.
- $C \subset L$ the set of flight legs that cross a count-line (e.g., 3:00 am)
- $I(f, s, t)$ the set of flight legs that are *inbound* to (f, s, t) , $\forall f \in F, \forall s \in S, \forall t \in T$.
- $O(f, s, t)$ the set of flight legs that are *outbound* from (f, s, t) , $\forall f \in F, \forall s \in S, \forall t \in T$.

Decision Variables

- x_{lf} a binary variable that is 1 if aircraft type f is assigned to leg l , $\forall l \in L, \forall f \in F$.
- y_{fst+} the number of aircraft of type f on the ground at station s just *after* flight event t , $\forall f \in F, \forall s \in S, \forall t \in T$.
- y_{fst-} the number of aircraft of type f on the ground at station s just *before* flight event t , $\forall f \in F, \forall s \in S, \forall t \in T$.

Objective:

$$\max \sum_{l \in L} \sum_{f \in F} c_{lf} x_{lf} \quad (1)$$

Subject to:

$$\sum_{f \in F} x_{lf} = 1 \quad \forall l \in L \quad (2)$$

$$y_{fst-} + \sum_{l \in I(f, s, t)} x_{lf} - \sum_{l \in O(f, s, t)} x_{lf} - y_{fst+} = 0 \quad \forall f \in F, \forall s \in S, \forall t \in T \quad (3)$$

$$\sum_{l \in C} x_{lf} + \sum_{s \in S} y_{is0-} \leq N_f \quad \forall f \in F \quad (4)$$

$$x_{lf} \in \{0, 1\} \quad \forall l \in L, \forall f \in F \quad (5)$$

$$y_{fst} \geq 0 \quad \forall f \in F, \forall s \in S, \forall t \in T. \quad (6)$$

Constraint (2) enforces the *cover* constraints, that is, each flight must be covered by exactly one aircraft type. Constraint (3) enforces aircraft *balance*: the total number of aircraft of a given type on the ground at a given station immediately prior to a flight event plus the number of aircraft of that type that land at that event must equal the number of aircraft of that type that leave that station at that event plus the number of aircraft that remain on the ground. These balance constraints, in conjunction with Equation (4), enforce *count*. Specifically, we use the concept of a *count-line* that represents a single point in time (typically a time of low activity, such as 3:00 a.m.). For each aircraft type, we force the number of aircraft of that type assigned to a flight spanning the count time plus the number of aircraft of that type on the ground at that station at the count time to not exceed the number of aircraft of that fleet type available. Because network balance is enforced, if we do not

exceed the fleet count at the count time, then we will not exceed it at any time.

Arc Copies

When assigning fleet types to flights, we would ideally like to match each flight to its optimal aircraft, that is, the one that best trades off between operating cost and capacity (and hence ability to capture revenue). However, such a match is not necessarily feasible for all flights because of the balance and count constraints. In practice, it has been observed that small shifts in the timings of the flight schedule can increase the feasible region of FAM, leading to solutions with reduced cost. In the simplistic example in Fig. 3, we consider two different departure timings for the flight from station DTW to station ATL. By choosing the earlier of the two departures in set $\{A\}$ out of DTW, we achieve coverage of two flights using a single aircraft of a given fleet type. That is, it is possible to cover both the flights from DTW to ATL and then from ATL to DTW with a single aircraft.

To take advantage of these potential benefits, Rexing *et al.* [44] introduced the *fleet assignment problem with time windows*. The idea is to allow small, discrete shifts in time to enable a better fleet assignment. FAM with time windows, as described here, is an example of the integration between fleet assignment and schedule design. Further integration approaches are illustrated in the section titled “Integrated Planning.” To formulate this problem, the time-space network is first modified to contain *arc copies*. Specifically, for each flight, we create

one arc for each possible time when the flight might depart. This is typically limited to a small window (e.g., 15 to 30 min before/after the originally scheduled departure time) so that dramatic changes in potential passenger demand will not be observed. Given this modified network, the basic FAM formulation must also be slightly modified. Specifically, the decision variables now represent choosing not only a fleet type for each flight but also a specific departure time. The objective is then given by Equation (7).

$$\min \sum_{f \in F} \sum_{l \in L} \sum_{n \in N_{lf}} c_{lf} x_{lfn}. \quad (7)$$

We replace constraint (2) with constraint (8), so that the cover constraint now selects not only a fleet type but a departure time as well. We also update the variable definition accordingly.

$$\sum_{f \in F} \sum_{n \in N_{lf}} x_{lfn} = 1 \quad \forall l \in L \quad (8)$$

$$x_{lfn} \in \{0, 1\} \quad \forall l \in L, \forall f \in F, \forall n \in N_{lf}. \quad (9)$$

Both the basic FAM and time windows version depend on the input parameters c_{lf} . In practice, to estimate these cost parameters can be difficult for many reasons, which motivates the need for more advanced FAMs.

Itinerary-Based Fleet Assignment (IFAM)

The objective function of FAM depends on the objective coefficients, c_{lf} , which capture both the cost and revenue component of a fleet assignment. The cost component can be

Figure 3. Example of the multiple arc formulation.

fairly straightforward to estimate, but the revenue component is much more difficult. It is usually thought of not as revenue captured but rather potential revenue that is lost, or *spilled*, due to insufficient capacity. For example, if 200 passengers want to buy tickets for a particular flight and that flight is assigned to a fleet type with only 170 seats, then the revenue from 30 passengers is lost. This spill cost is added to the operating cost to determine the coefficients c_{lf} .

There are several challenges associated with calculating spill. The first is the fact that demand is dynamic. Only one fleet type will be chosen for the entire schedule period, but demand will vary daily over this period. An even bigger challenge is the fact that passengers do not just fly individual flights, but often fly multileg itineraries. By only looking at individual legs in FAM, we miss the interdependencies that stem from these itineraries. For example, suppose a passenger wants to fly from Boston to Los Angeles via Chicago. If the basic FAM model is solved, a large aircraft may be assigned to the Boston to Chicago flight with more than enough capacity to meet all demand. If the flight from Chicago to Los Angeles is assigned to an aircraft with inadequate capacity, however, the passenger may be spilled from this flight. In reality, we would lose the revenue of this passenger from both flights; in the model, we would still capture their revenue on the first leg, even though they were spilled from the second.

To address this, Barnhart *et al.* [11] developed the following extended version of FAM, known as *itinerary-based fleet assignment* (IFAM). In this approach, the fleet assignment decisions are augmented with passenger “spill variables” that take into account the demand for each itinerary rather than each flight leg. Specifically, a fleet assignment also implicitly defines the capacity on each flight leg. Given this capacity, IFAM can simultaneously determine the number of passengers spilled (i.e., potential passengers whose revenue is lost due to inadequate capacity) and corresponding revenue lost across the entire itinerary, not on an individual flight leg. Although there are still many challenges with this approach (e.g., it ignores the fact

that passenger purchases occur over a rolling time horizon and cannot be fully controlled by the airline), it nonetheless is a substantial step toward overcoming the limitations of a leg-based approach.

Parameters

$SEATS_f$	the number of seats available on aircraft of fleet type f , $\forall f \in F$.
$\widetilde{fare}_p$	the fare for itinerary p , $\forall p \in P$.
b_p^r	recapture rate from p to r , that is, the fraction of passengers spilled from itinerary p that the airline succeeds in redirecting to itinerary r , $\forall p \in P, \forall r \in P$.
CAP_l	is the capacity of the aircraft assigned to leg l , $\forall l \in L$.
δ_l^p	1 if itinerary p includes flight leg l and is 0 otherwise, $\forall l \in L, \forall p \in P$.

Decision Variables

t_r^p	the number of passengers requesting itinerary p that are redirected by the model to itinerary r , $\forall p \in P, \forall r \in P$.
---------	--

We augment the FAM formulation by replacing the objective with Equation (10) and adding constraints (11)–(13).

Modified objective:

$$\min \sum_{l \in L} \sum_{f \in F} c_{lf} x_{lf} + \sum_{p \in P} \sum_{r \in P} (\widetilde{fare}_p - b_p^r \widetilde{fare}_r) t_r^p \quad (10)$$

Additional constraints:

$$\begin{aligned} \sum_{f \in F} SEATS_f x_{lf} + \sum_{p \in P} \sum_{r \in P} \sigma_l^p t_r^p \\ - \sum_{r \in P} \sum_{p \in P} \sigma_l^p b_p^r t_r^p \geq Q_l - CAP_l \quad \forall l \in L \end{aligned} \quad (11)$$

$$\sum_{r \in P} t_r^p \leq D_p \quad \forall p \in P \quad (12)$$

$$t_r^p \geq 0 \quad \forall r \in P. \quad (13)$$

In the augmented model, we not only assign fleet types to flights (thereby determining the capacity on each leg) but also choose the number of passengers to assign

to each itinerary through constraint set (11). We note here that the parameters (SEATS_f) indicates the number of seats available on aircraft type f , which is followed by our decision variable, x_{if} . On the right side of this equation, we represent the demand, Q_i , as defined in Equation (14) and subtract from it the available capacity for the particular leg, CAP_l . Finally, Equation (12) ensures that we do not assign more passengers to an itinerary than there is demand, and Equation (13) ensures that we do not assign negative numbers of passengers.

$$Q_i = \sum_{p \in P} \delta_i^p D_p. \quad (14)$$

Most recently, Dumas and Soumis [12] and Dumas *et al.* [45] have provided additional research on how to estimate and model itinerary-based passenger demand and its effect on the quality of FAM solutions.

AIRCRAFT ROUTING

Once flights have been assigned to specific fleet types, the subsequent planning problems can be partitioned into independent sets. For each fleet type, we next solve an *aircraft routing* (AR) problem, as described in Gopalan and Talluri [46] and Clarke *et al.* [47]. The primary goal of AR is to ensure that every aircraft has adequate opportunity to undergo the required routine maintenance. For example, in the United States, an A check must be completed after every 65 flight hours; any aircraft exceeding this limit will be grounded by the FAA. Several months before a new schedule begins, carriers therefore build *lines-of-flight* (LOF). These sequences dictate a consequence series of flights to be flown by a single aircraft. Aircraft routes can then be constructed by connecting LOF that start and end with maintenance events, while ensuring maintenance feasibility over the flights in between.

In constructing OFs, *flight connections* are established as well. When two consecutive flights are flown by a common aircraft, this provides opportunities for improved passenger itineraries and crew schedules (as there is no need to change planes between flights),

and also has implications for gate scheduling and similar operational activities.

Note that at this stage, specific aircraft (also known as *tails* because they are identified by the unique number painted on the tail of the aircraft) are not assigned to the maintenance routes. Although the intent is to repeatedly fly the same routes over the course of the schedule, these routes will not always be flown by the same aircraft. This is in part to balance the utilization of aircraft over the system, but more importantly it is a reflection of the operational deviations that often occur in practice. For example, as illustrated in Fig. 4, suppose flights A and B are scheduled to arrive at the same station at roughly the same time, and then their aircraft will be used for departures C and D, respectively. If A is delayed in arrival, an operational decision may be made to use the aircraft from B for C instead of D, as was originally scheduled (for example, to ensure that passengers on C can make international connections that they would otherwise miss). In doing so, the aircraft routes have been swapped, with the aircraft from A now flying B's route and vice versa. In the process, because the different aircraft have different histories (e.g., one may have already flown more hours since its last maintenance than the other), the new routings may be maintenance infeasible.

Although processes vary substantially by carrier, it is not uncommon for the assignment of specific tails to routes to occur on a rolling horizon five to seven days before the day of operation. Each day these assignments are modified both to add a new day to the end of the horizon and also to modify the existing routes to take into account any changes such as aircraft swaps and unplanned maintenance needs.

For more information, we refer the reader to Gabteni and Grönkvist [48].

Aircraft Routing Models

There are several different ways to model and solve the aircraft routing problem, each with different benefits and challenges and each appropriate for different carriers and different contexts. For example, Gopalan and Talluri [46], Kabbani and Patty [49],

Figure 4. Recovery swaps under disruption.

and Talluri [50] present some of the seminal early work in this area that focuses on challenges such as building aircraft routings that spend every third or fourth night in a maintenance station (i.e., an airport with maintenance capabilities) so that short-term maintenance checks can be completed on a regular basis. This work draws largely from graph theory and the development of Euler tours. Clarke *et al.* [47] pose the problem as being similar to an asymmetric traveling salesman problem (TSP) [51], which they solve using a Lagrangian relaxation [52] and subgradient optimization techniques.

We focus here on two particular modeling approaches, one based on *multicommodity flow (MCF)* formulation techniques, and the other on *string-based* models.

Multicommodity Flow Formulations

More recent formulations of the aircraft routing problem have focused on traditional, linear programming formulations. As detailed in Grönkvist [53], the maintenance-routing problem can be formulated as a variation of the *MCF* problem. In the general *MCF* problem [54,55], we are given a set of commodities, a set of nodes (each with a supply or demand for each commodity), and a set of arcs. The objective is to find the least-cost way

to move commodities across the network from supply to demand while satisfying capacity constraints on the individual arcs.

Sets

F the set of all flights (recall that AR is solved separately for each fleet type).

Parameters

c_{ij} the cost of assigning the connection i to j . This cost often represents the (negative of) potential additional revenue that can be gained by offering this flight connection as a direct flight with no change of planes. In actuality, carriers are usually more concerned with feasibility than optimality when solving the aircraft routing problem.

Decision Variables

x_{ij} a binary variable that indicates if flight i is followed by flight j and 0 otherwise.

Objective:

$$\min \sum_{i \in F} \sum_{j \in F} c_{ij} x_{ij} \quad (15)$$

Subject to:

$$\sum_{j \in F} x_{ij} = 1 \quad \forall i \in F \quad (16)$$

$$\sum_{j \in F} x_{ij} - \sum_{j \in F} x_{ji} = 0 \quad \forall i \in F \quad (17)$$

$$x_{ij} \in \{0, 1\} \quad \forall i \in F, \forall j \in F. \quad (18)$$

To formulate aircraft routing as a variation of MCF, we define a network in which each commodity is an aircraft route, each flight is represented by a node, and an arc exists between each pair of nodes corresponding to flights that form a feasible connection. Constraints (16) require each flight to be covered exactly once (i.e., to be included in exactly one route). Constraints (17) enforce balance. Additional constraints are used to enforce maintenance feasibility as implemented by Grönkvist [53].

String-Based Models

The challenge of the MCF formulation lies in capturing all maintenance requirements. Therefore, as an alternative, several researchers have taken a string-based modeling approach to solve aircraft routing, often in the context of integrating AR with other planning problems [56,57].

In the string-based approach, a variable corresponds to the assignment of a particular route to a complete “string,” that is, a complete LOF. Each string has an associated cost that spans the entire set of assignments in that string. Constraints primarily focus on building continuous aircraft routes out of strings; the maintenance constraints by definition are enforced through the variable definition, with a variable not being included in the model unless the corresponding string is maintenance feasible. The following is an example of a string-based model.

Sets

- S the set of all possible strings.
- F the set of flights.
- N the set of nodes that represent time and space points in the flight network.
- $S(s, n)$ the set of strings s that start at node n , $\forall n \in N, \forall s \in S$.
- $E(s, n)$ the set of strings s that end at node n , $\forall n \in N, \forall s \in S$.

Parameters

- K a parameter that indicates the number of available aircraft.
- α_{fs} a binary parameter that indicates if string s contains flight f , $\forall s \in S, \forall f \in F$

Decision Variables

- g_n variables that represents ground arcs, which indicate the number of aircraft on the ground at node point n , $\forall n \in N$.
- d_s a binary variable that indicates if string s is chosen in the final solution, $\forall s \in S$.

$$\min \sum_{s \in S} c_s d_s \quad (19)$$

Subject to:

$$\sum_{s \in S} \alpha_{fs} d_s = 1 \quad \forall f \in F \quad (20)$$

$$\sum_{s \in E(s, n)} d_s + g_n^- - \sum_{s \in S(s, n)} d_s - g_n^+ = 0 \quad \forall n \in N \quad (21)$$

$$\sum_{s \in S} d_s + \sum_{n \in Z^T} g_n^+ \leq K \quad (22)$$

$$d_s \in \{0, 1\} \quad \forall s \in S \quad (23)$$

$$g_n^+, g_n^- \geq 0 \quad \forall n \in N. \quad (24)$$

The objective in Equation (19) minimizes the cost of the chosen strings. Constraint set (20) ensures that each flight is included in exactly one chosen string, with α_{fs} indicating whether string s covers flight f . Constraint set (21) ensures that continuous aircraft routes can be formed from the given strings (note that the mapping from strings to routes may not be unique). Finally, constraint set (22) provides a count constraint. As in the FAMs, the total number of available strings that are assigned at a given time cannot exceed the number of aircraft available.

The challenge in solving a string-based formulation is the exponentially large number of variables. One approach to overcome this challenge is to solve the LP relaxation of the problem via *column generation* [58]. In column generation, a *restricted master problem* is provided in which a limited subset of

the variables (here, the strings) are included. This restricted master is solved to optimality. The dual information is then passed on to a *subproblem*, a secondary optimization problem that is used to identify the string with the most negative reduced cost. If this yields a string with strictly negative reduced cost, then this can be passed back to the restricted master that will then continue with pivoting. Otherwise, if there are no negative reduced cost strings then the optimality of the problem has been established.

The key challenge in this approach is to find an efficient way to solve the subproblem. This can be done, for example, by formulating and solving a network flow problem (similar to the MCF approach above), where the arc costs now include the dual information as well as the true costs.

CREW SCHEDULING

Just as aircraft are required to follow a complex set of maintenance requirements, there are also many rules that restrict how crews can be assigned to flights. For example, on a given work day (known as a *duty*), crew members are limited in both the total number of hours that they can fly and also the total *elapsed time* from the start of the duty's first flight to the end of the duty's last flight. There are also limits on the minimum and maximum time between any two consecutive flights. In addition, crew members often are on duty for multiple sequential days. Their multiday schedule is known as a *pairing*. A pairing is simply a string of consecutive duties, where the first duty starts and the last duty ends at the airport where the crew is *based*, and nights in between the duties are spent at a hotel. A pairing also has many restrictions on the amount of flying and on-duty time permitted, as well as on the amount of rest required between duties. More information on crew restrictions can be found in Barnhart *et al.* [59].

In addition to these complex feasibility rules, the cost structure for paying crews is quite complex as well. For example, the cost of a duty is defined by equation (25).

$$b_d = \max\{mg_1, f_1 \times \text{elapsed}, \text{fly}\} \quad (25)$$

Here mg_1 represents a guaranteed minimum number of hours. For example, if a crew flies a short flight, followed by a substantial wait time on the ground, followed by another short flight, the number of compensated flying hours could be minimal. To prevent such a situation from occurring, each crew is paid at least mg_1 , which represents a lower threshold on the number of hours. In addition, f_1 represents a contractual fraction that is multiplied by the total elapsed duty period, to ensure adequate compensation for a duty period of very limited duration. Finally, fly represents the total number of flying hours in a duty period.

$$c_p = \max \left\{ \text{NDP} \times mg_2, f_2 \times \text{TAFB}, \sum_{d \in P} b_d \right\}. \quad (26)$$

In the first term, NDP represents the number of duties in a pairing. This is multiplied by mg_2 , which is the minimum guarantee per duty. Next, f_2 is again a contractual fraction that is then multiplied by the time-away-from-base (TAFB). The final term represents the total of all of the individual duty periods as computed in Equation (25).

Given the cost functions stated above, the crew scheduling problem thus becomes one of finding a minimum-cost assignment of crews to flights while satisfying all of these feasibility requirements. See Barnhart *et al.* [59] for a more detailed discussion of this complex problem.

Crew scheduling has many parallels to aircraft routing in the sense of assigning resources to sequences of flights while ensuring a number of complex constraints. And like aircraft routing, crew scheduling is solved in two stages. In the first stage, several months in advance of the start of the upcoming schedule, a set of *pairings* is constructed that collectively covers all of the flights. These pairings (analogous to the LOF in aircraft routing) will be repeated throughout the schedule period, but not always by the same crew members (just as LOFs are flown by different tails on different days). It is not until the second stage (typically solved on a monthly basis) that specific crew members are actually assigned to these pairings (analogous

to the tail assignment problem in aircraft routing). This assignment of crews to pairings is typically solved through either a *crew rostering problem* or a *bidline problem*. For more information on these problems we refer the reader to Caprara *et al.* [60]. We focus for the remainder of this section on the crew pairing problem.

Crew Pairing Formulation

A crew pairing is a fully self-contained assignment for an individual crew member. That is, given the set of pairings that make up a crew member's monthly schedule, if each pairing is feasible then the full schedule will be feasible. Furthermore, the cost of a schedule is simply the sum of the costs of the pairings.

Thus, we can formulate the crew pairing problem quite simply as a *set partitioning problem* [61] in which each variable represents a feasible pairing. The sole constraint is to choose a set of pairings such that each flight is included in exactly one pairing.

Sets

- P the set of all possible strings.
- F the set of flights.

Parameters

- δ_f^p a binary parameter that indicates whether flight f is included in pairing p , $\forall f \in F, \forall p \in P$.

Decision Variables

- x_p a binary variable that indicates if pairing p is included in the solution, $\forall p \in P$.

Objective:

$$\sum_{p \in P} c_p x_p \quad (27)$$

Subject to:

$$\sum_{p \in P} \delta_f^p x_p = 1 \quad \forall f \in F \quad (28)$$

$$x_p \in \{0, 1\} \quad \forall p \in P. \quad (29)$$

In constraint set (28), the parameter δ_f^p is a binary parameter that indicates whether flight f is included in pairing.

Note that although this problem is very concise to formulate, it can be quite difficult to solve for a moderately sized airline; the number of feasible pairings (and thus binary variables in the model) can easily reach billions. Again, similar to the aircraft routing, this problem is often solved using column generation to solve the linear programs (for an alternative solution technique, see Vance *et al.* [62]).

When solving the LP relaxation of the crew pairing problem via column generation, it is necessary to pose a subproblem in which we generate the pairing with the most negative reduced cost. This is more challenging than the aircraft routing subproblem because of the parameters of the complex feasibility rules as well as the non-linear cost function, both of which cannot simply be summed across the flights in a pairing. To overcome these challenges, one of the most successful approaches has been through *multilabel shortest path* algorithms [63]. These approaches are similar to Dijkstra or other label setting algorithms, with the key distinction being that at each node, rather than just keeping one cost label and pruning any path to that node with a higher cost, we must keep multiple labels (e.g., one for cost, one for elapsed time in the duty accrued so far, and one for flying time in the duty accrued so far), and we can only prune when *all* labels are dominated.

Finally, we conclude this section with a discussion of branching strategies. When using column generation to solve string-based models such as aircraft routing or crew scheduling, a subproblem is used to generate candidate pivot variables, rather than explicitly enumerating all of the variables and computing their respective reduced costs. Note that this approach only solves the LP relaxation of the problem. When column generation is embedded within *branch and bound* to solve an integer program, it is often referred to as *branch and price* [58]. Using column generation within *branch and bound* introduces its own new set of challenges, as we need to be able to enforce

a branching strategy that is consistent with the subproblem formulation. This is not necessarily a trivial task. For example, in traditional branching strategies, we often pick some variable that has a fractional value and impose additional constraints to rule out this value. If x is a binary variable with value 0.5 in the current solution to the LP relaxation, we might enforce $x = 0$ on one half of the tree and $x = 1$ on the other. These new constraints impose an additional dual value in the reduced cost calculation for variable x however, which is not easily captured without modifying the subproblem structure to treat that variable as a special case.

As an alternative, we can use a strategy known as *branching-on-follow-ons* [64]. We explain this strategy via a simple example. Suppose we have a pairing composed of four sequential flights, $A \rightarrow B \rightarrow C \rightarrow D$, and that this pairing is assigned to a fractional value. To prevent this fractional solution in subsequent nodes of the tree, we do not branch on the fractional pairing variable, but rather on a fractional flight connection. For example, we can force A to be followed by B in one half of the tree and A *not* to be followed by B in the other half. Forcing A to be followed by B can be imposed by simply combining the nodes representing the two flights into one single node, while forcing A to be followed by B can be imposed by simply deleting the arc connecting the nodes corresponding to these flights. The structure of the subproblem remains unchanged, and in fact each progressive subproblem becomes easier to solve, as more connections are forced a priori.

We conclude by noting that this branching strategy extends to set partitioning problems in the broader sense, where we can branch on items A and B *are* in the same set on one side of the tree and A and B *are not* in the same set on the other.

BEYOND BASIC PLANNING

Integrated Planning

There is clearly a strong link between each of the three planning problems described above (as well as with the schedule design problem, in which the set of flights itself is

determined). Significant benefits can therefore be achieved through an integrated rather than sequential approach to solving them. On the other hand, given that each problem is itself challenging to solve individually, solving them simultaneously requires significant advances in modeling and algorithms in order to ensure tractability.

Over the past 15 years, many advances have been made in this area, with two primary focuses. One is in developing heuristics to quickly find high-quality solutions to large-scale integer programs. The other is in partial integration, trying to identify the most critical relationships between different problems and focusing on capturing these relationships in an integrated approach. The following is merely a sampling of this rich literature.

In Clarke *et al.* [65], the basic fleet assignment problem is extended to include maintenance and crew considerations. That is, although FAM is still solved prior to aircraft routing and crew scheduling, extra constraints are added to increase the likelihood that the FAM solution will be maintenance- and crew-feasible.

In Sherali *et al.* [66] fleet assignment is augmented with additional schedule design decisions, and the focus is on computational techniques to solve the resulting large-scale integer program. Schedule design and fleet assignment are also integrated in Lohatepanont and Barnhart [67] and Barnhart *et al.* [68].

Finally, we note that there have been several papers on the integration of aircraft routing and crew scheduling, exploiting the fact that the link between these two problems is fairly narrow—the key connection is that when two flights with a very tight connection time are assigned to a common aircraft, then these two flights become a viable connection for a crew as well. (If the flights were assigned to two different aircraft, there would not be time for the crew to move through the terminal and cover both flights.) Thus decisions made in the aircraft routing problem impact the feasible region of decisions to be made in the crew scheduling problem. This problem structure naturally lends itself to a variety of decomposition approaches. These are explored by Cohn and Barnhart [56], Mercier

et al. [57], Cordeau *et al.* [69], Mercier and Soumis [70], and Weide *et al.* [71].

Robustness and Recovery

It is important to note that airline planning problems are often modeled as static and deterministic, although the real-world problems are both dynamic and stochastic. For example, the same fleet assignment is flown repeatedly over the course of a schedule period, even though demand varies daily over this horizon. Furthermore, the flight times needed to define the time-space network are taken as fixed, whereas actual flight times can vary quite substantially in practice.

The reasons for static and deterministic modeling are twofold. The first is that repeating schedules have operational benefits, reducing the number of decisions that must be made and communicated, and allowing workers to develop familiarity with a plan over time. The second is that even when solved statically and deterministically, these problems are computationally very challenging.

The cost of these simplifying assumptions is that it is quite common that a carrier will be unable to fully operate a schedule as planned on any given day. Maintenance problems, weather delays, and many other sources of disruption will require modifications to the original plan to recover from these disruptions. There are two ways to reduce the impact of disruptions.

One is through sophisticated recovery tools that allow the user to quickly modify the current schedule in response to a disruption. There is a vast literature on this topic. The aircraft recovery problem is formalized in Rosenberger *et al.* [72] and is further studied in Eggenberg *et al.* [16]. For more information on disruption management, Clausen *et al.* [73] provide a survey paper that covers aircraft recovery, crew recovery, and integrated crew aircraft and passenger recovery. Sarac *et al.*, in their work [74], use column generation approach to deal with day-of-operations disruption and subsequent recovery.

The second approach is to incorporate *robustness* into the planning process. This can take the form of reducing the impact of

delays (e.g., adding buffer between flights decreases the likelihood that one flight delay will propagate to a subsequent down-stream flight) [34]. It can also take the form of creating greater opportunities for recovery when disruptions do occur (e.g., building crew pairings that provide extra swap opportunities when an inbound crew is delayed and enabling another crew to take over the delayed crew's outbound flight) [75,76].

We conclude by highlighting a few recent approaches to improving robustness in airline planning:

- Rosenberger *et al.* [77] note that when airlines cancel flights, they tend to cancel entire cycles, that is, sequences of flights that begin and end at the same airport. As a result, a fleet assignment and aircraft rotation with many short cycles is frequently less sensitive to a flight cancellation than one with only a few short cycles.
- Ahmadbeygi *et al.* [34] quantify the prevalence of delay propagation in modern airline schedules. This provided motivation for the work of Ahmadbeygi *et al.* [78], in which minor modifications are made to flight departure times to redistribute the network's existing slack, moving extra slack to turns that are historically prone to delay propagation and away from turns that are historically reliable. This work builds on that in Lan *et al.* [79] and most recently on that in ISMP [80].
- The motivation behind the work in Lapp and Cohn [81] is the fact that tail assignments are frequently swapped over the course of the day to adjust for disruptions. This can make longer term maintenance plans infeasible. This paper takes an existing set of LOFs and modifies them so as to maintain important crew and passenger connections, while maximizing the number of opportunities for overnight recovery of the maintenance plan.
- In Schaefer *et al.* [82], simulation (in the form of a tool called SimAir) is used

to evaluate the quality of crew schedules when implemented under stochastic conditions.

- Ehrgott Ryan [83], Tekiner *et al.* [15], and Yen and Birge [84] explore the construction of robust crew schedules under uncertainty.
- The authors use the idea of a *station purity* measure to improve the robustness of fleet assignments in Smith and Johnson [85].
- Weide *et al.* [71] provide an iterative approach to generating integrated aircraft routing and crew scheduling. By first solving one problem to optimality, the authors are able to obtain trade-off points between cost and robustness.

FUTURE WORK

Despite all of the efforts and accomplishments that the OR community has had in passenger aviation, many challenges still remain. These include further advances in robust and integrated planning, as well as many other problems including those briefly introduced in this article.

In addition, the industry faces many new challenges, which the OR community can help to address by playing a pivotal role. These include the following:

- escalating and volatile fuel costs;
- increasing congestion, both at airports and in the airspace;
- environmental concerns; and
- security concerns.

We expect to see many advances in addressing these challenges in the coming years.

ALLOCATION GAMES

BRIAN ROBERSON
Department of Economics,
Krannert School of
Management, Purdue
University, West
Lafayette, Indiana

INTRODUCTION

This article examines a class of resource allocation games in which two budget-constrained players strategically allocate resources across multiple simultaneous contests (see also the article titled ***TPZS Applications: Blotto Games*** in this encyclopedia). In each of the individual component contests the players allocate scarce resources (such as time, money, or effort) in order to affect the probability of winning the contest, where this probability is increasing in a player's own sunk resource expenditure and decreasing in their opponent's resource expenditure in that contest (for an introduction to contest theory, see Konrad [2]). The outcome of the allocation game is a function of the outcomes in the individual component contests. Two of the most common objectives in such environments are (i) to maximize the sum of the winnings across the individual contests, henceforth the *plurality objective*, and (ii) to maximize the probability of winning a majority of the component contests, henceforth the *majority objective*.¹

There are a number of important applications that may be characterized as

budget-constrained players strategically allocating resources across multiple simultaneous contests. Blackett [4], in a 1953 panel that was chaired by Oskar Morgenstern and highlighted this particular class of resource allocation games, lists several military applications including (i) the allocation of bombers and interceptors across a set of target areas, (ii) the routing of convoys and the choice of submarine locations across disjoint routes, (iii) the location of amphibious landings and the allocation of defensive forces, and (iv) the allocation of forces across a set of distinct battlefields. Clearly, military applications of the model are plentiful. However, the problem of allocating resources across multiple component contests also arises in economic and political applications. For example, in a presidential campaign there are a number of combinations of states that result in an Electoral College victory, and each candidate allocates his or her campaign resources across the states in an attempt to win a majority of the votes within each of the states in any one of the winning combinations. Other applications of this theoretical framework include political competition over taxation and redistribution, political competition over vote-buying, multidimensional research and development competition, and multimarket advertising resource allocation.

Partly because it is a foundational problem that is well suited for abstract theoretical modeling, multidimensional strategic resource allocation was one of the first problems examined in modern game theory. Borel [5] formulates this problem as a constant-sum game involving two symmetric players, A and B, who must each allocate a fixed amount of resources, normalized to one unit of resources, over three contests (or battlefields). Each player must distribute their resources without knowing their opponent's distribution of resources. In each of the component contests, the player who allocates the higher level of resources wins the contest, and

¹For a survey of multidimensional contests in which there exist linkages in how battlefield outcomes and costs aggregate in determining performance in the overall conflict, see Kovenock and Roberson [3].

each player maximizes the expected number of component contest wins.²

Borel's game, which came to be known as the *Colonel Blotto game*, was a focal point in the early game theory literature [6–10]. To some degree, this was due to the fact that the Colonel Blotto game is, as Golman and Page [11] describe, an “elaborate version of Rock, Paper, and Scissors.” For example, in the symmetric Colonel Blotto game with three contests, each player i chooses three numbers $(x_{i,1}, x_{i,2}, x_{i,3})$ such that $\sum_{j=1}^3 x_{i,j} = 1$. If player i wishes to increase his allocation of force to contest j , then he must decrease his allocation of force to either or both of the other two contests. Furthermore, if player A knew player B's allocation of resources $(x_{B,1}, x_{B,2}, x_{B,3})$, then, because within each component contest the player who allocates the higher level of resources wins that contest, player A could win two of the three contests. As a result, the Colonel Blotto game (as with the Rock, Paper, and Scissors game) has no pure-strategy equilibria. In this game, a mixed strategy is a joint distribution function that specifies both the randomization in the allocations to the individual component contests (provided by a univariate marginal distribution function for each of the component contests) and a correlation structure that ensures that across the set of resource allocations the budget constraint is satisfied with probability one.

From a theoretical point of view, the Colonel Blotto game also provides an important benchmark for multidimensional strategic resource allocation games.³ In particular, let $p_{i,j}(x_{i,j}, x_{-i,j})$, henceforth the

contest success function (CSF), denote the probability that player i wins component contest j when player i allocates $x_{i,j}$ resources and player $-i$ allocates $x_{-i,j}$ resources to component contest j , and consider the general ratio-form contest success function $p_{i,j}(x_{i,j}, x_{-i,j}) = x_{i,j}^m / (x_{i,j}^m + x_{-i,j}^m)$, where the parameter $m \geq 0$ specifies the level of randomness or noise in the component contests. When $m = 0$, each player wins each component contest with equal probability regardless of the players' resource allocations. For low values of m the outcome of the component contest is largely random, or noisy (for further information on how much noise is implied, see Konrad and Kovenock [14]). As m increases, the amount of noise in the contest decreases. Now, consider a Blotto-type resource allocation game in which (i) each player maximizes the expected number of component contest wins, (ii) in each of the n component contests, the probability that player i ($i = A, B$) wins component contest j ($j = 1, \dots, n$) is given by the general ratio-form CSF, and (iii) each player has one unit of resource to distribute among the n contests. For this resource allocation game, the Lagrangian for player i 's optimization problem may be written as,

$$\pi_i(\mathbf{x}_i, \mathbf{x}_{-i}) = \sum_{j=1}^n \left[\frac{x_{i,j}^m}{x_{i,j}^m + x_{-i,j}^m} - \lambda_i x_{i,j} \right] + \lambda_i, \quad (1)$$

where $\mathbf{x}_i$ and $\mathbf{x}_{-i}$ are elements of the standard simplex in $\mathbb{R}^n$. Recalling that the Colonel Blotto game features deterministic, or no noise, component CSFs in which the player who allocates the higher level of resources wins that contest,⁴ it is clear that the Colonel Blotto game corresponds to the limiting case of this game in which m is set to infinity. This resource allocation game has also been examined by Friedman [17] for the case that $m = 1$,

²Although Borel actually assumes that the players maximize the probability of winning a majority of the component contests, in the case of symmetric players and three contests the majority objective is strategically equivalent to the plurality objective. Furthermore, with four or more contests, the solution to the majority game is still an open question. Following Gross and Wagner [6], the literature on multidimensional contests has primarily focused on the plurality objective.

³The discussion given here focuses on the general ratio-form CSF. Note, though, that a similar argument can be made for the difference-form CSF as

in Lazear and Rosen [12]. For further details, see Che and Gale [13].

⁴This type of CSF is commonly known as the *auction CSF*. See, for example, the closely related literature on all-pay auctions [15,16].

and by Robson [18] for the case that $m \in (0, 1]$. Observe that Equation (1) is concave with respect to $\mathbf{x}_i$ only for m less than or equal to 1. Furthermore, for m greater than 2, as in the $m = \infty$ case, no pure-strategy equilibria exist. Even in the case of a single contest with linear costs, the equilibrium set for the $m > 2$ case has not yet been characterized, except in the case of $m = \infty$ [16]. Note also that in the single contest game with linear costs, it is known that for $m > 2$ there exist equilibria that are payoff equivalents to the $m = \infty$ case [19,20]. To summarize, the equilibrium characterization of the Colonel Blotto game (i.e., the $m = \infty$ case) provides an important theoretical benchmark that sheds light on all specifications of the general ratio-form CSF game in which $m > 2$.

The remainder of this article is outlined as follows. The section titled “The Model” presents the formal specification of the Colonel Blotto game. The section titled “The Colonel Blotto Game (Plurality Objective)” provides an introduction to the Colonel Blotto game with a focus on the intuition for the key results. Partly for the reasons mentioned above and partly because of several theoretical breakthroughs in the area of multidimensional contests, there has been a resurgence of interest in the Colonel Blotto game [21–32]. The section titled “Variations and Extensions” briefly summarizes several of these recent developments including nonconstant-sum formulations of the Colonel Blotto game, additional restrictions on the strategy space, a simplified form of the Colonel Blotto game, and majoritarian and other objectives. The final section concludes the article.

THE MODEL

In this section we present a framework for examining various multidimensional strategic resource allocation games of the Blotto type. Two players, A and B , simultaneously allocate resources across a finite number, $n \geq 3$, of independent component contests. Each player has a fixed level of available resources (or budget). The stronger player A has a normalized budget of 1 unit of resources, and the

weaker player B has a normalized budget of $\beta \leq 1$. Each component contest $j \in \{1, \dots, n\}$ has a value of v_j for each player. We will focus primarily on the case that $v_j = v_k$ for each $j, k \in \{1, \dots, n\}$, a condition henceforth referred to as *homogenous contests*, but will also examine the case in which this condition does not hold, henceforth referred to as the case of *heterogenous contests*.

Let $\mathbf{x}_i$ denote the n -tuple $(x_{i,1}, \dots, x_{i,n})$ of player i 's allocation of resources across the component contests. The level of resources allocated to each contest must be nonnegative. For player A , the set of feasible allocations of resources across the n component contests is denoted by

$$S_A = \left\{ \mathbf{x} \in \mathbb{R}_+^n \mid \sum_{j=1}^n x_j = 1 \right\}.$$

Player B 's set of feasible allocations of resources, denoted S_B , is similarly delineated by $\mathbf{x} \in \mathbb{R}_+^n$ such that $\sum_{j=1}^n x_j = \beta$. We will focus primarily on the case that the resource is continuous, but will also briefly examine additional restrictions on the strategy space.

Objectives

Let $\pi_{i,j}(x_{i,j}, x_{-i,j})$ denote the payoff to player i in contest j when player i allocates $x_{i,j}$ resources and player $-i$ allocates $x_{-i,j}$ resources to contest j . Within each component contest the player that allocates the higher level of resources wins, and in the case of a tie, each player wins the component contest with equal probability. That is,

$$\pi_{i,j}(x_{i,j}, x_{-i,j}) = \begin{cases} v_j & \text{if } x_{i,j} > x_{-i,j} \\ \frac{v_j}{2} & \text{if } x_{i,j} = x_{-i,j} \\ 0 & \text{if } x_{i,j} < x_{-i,j}. \end{cases}$$

We will focus primarily on the general form of the *plurality objective* in which each player i 's payoff across the set of component contests, denoted π_i , is equal to the sum of the winnings in the individual component contests:

$$\pi_i(\mathbf{x}_i, \mathbf{x}_{-i}) = \sum_{j=1}^n \pi_{i,j}(x_{i,j}, x_{-i,j}),$$

in this case the game is constant-sum with a total value of $\sum_{j=1}^n v_j$. Note that when $v_j = 1$ for all j , $\pi_i(\cdot, \cdot)$ is equal to the number of contests that player i wins.

We will also address several alternative objectives such as the *majority objective* in which each player i 's payoff across the set of component contests, denoted $\hat{\pi}_i$, is given by

$$\hat{\pi}_i(\mathbf{x}_i, \mathbf{x}_{-i}) = \begin{cases} 1, & \text{if } \sum_{j=1}^n \pi_{i,j}(x_{i,j}, x_{-i,j}) > \frac{\sum_{j=1}^n v_j}{2} \\ \frac{1}{2}, & \text{if } \sum_{j=1}^n \pi_{i,j}(x_{i,j}, x_{-i,j}) = \frac{\sum_{j=1}^n v_j}{2} \\ 0, & \text{otherwise} \end{cases}$$

in this case the game is constant-sum with a total value of 1.

Strategies

For each player i , a pure strategy is a budget-balancing n -tuple consisting of a nonnegative allocation of resources to each of the n component contests. A mixed strategy, which we term a *distribution of resources*, for player i is an n -variate distribution function $P_i : \mathbb{R}_+^n \rightarrow [0, 1]$ with support (denoted $\text{Supp}(P_i)$) contained in player i 's set of feasible resource allocations $\mathcal{S}_i$ and with the set of one-dimensional marginal distribution functions $\{F_{i,j}\}_{j=1}^n$, one univariate marginal distribution function for each component contest j . In a mixed strategy, the n -tuple of player i 's allocation of resources to each of the n contests is a random n -tuple drawn from the n -variate distribution function P_i .

THE COLONEL BLOTTO GAME (PLURALITY OBJECTIVE)

Throughout this section we will focus on the plurality objective. We begin with the symmetric Colonel Blotto game (i.e., $\beta = 1$) with homogeneous contests ($v_j = v_k \ \forall j, k \in \{1, \dots, n\}$). Let $v(\equiv v_j)$ denote the common value for each of the n component contests and let $\mathcal{S}(\equiv \mathcal{S}_A = \mathcal{S}_B)$ denote the symmetric strategy space.

Symmetric Players and Homogeneous Contests

In the case of symmetric players and homogeneous contests, it is straightforward to show that there is no pure-strategy equilibrium. Borel and Ville [33] provide an equilibrium in the case of three-component contests. Gross and Wagner [6] extend the analysis of the symmetric game with homogeneous contests to allow for $n \geq 3$ and $n = 2$. Theorem 1 provides Gross and Wagner's [6] sufficient conditions for equilibrium in the symmetric Colonel Blotto game with homogeneous contests.

Theorem 1 [Gross and Wagner [6]]. *The pair of n -variate distribution functions P_A^* and P_B^* constitute a Nash equilibrium of the symmetric Colonel Blotto game with homogeneous contests if they satisfy the following two conditions: (i) For each player i , $\text{Supp}(P_i^*) \subset \mathcal{S}$ and (ii) P_i^* , $i = A, B$, provides the corresponding set of univariate marginal distribution functions $\{F_{i,j}^*\}_{j=1}^n$ outlined below.*

$$\forall j \in \{1, \dots, n\}, \quad F_{i,j}^*(x) = \frac{x}{\frac{2}{n}}, \quad \text{for } x \in [0, \frac{2}{n}].$$

There exist such strategies, and, in equilibrium, each player has an expected payoff of $(nv/2)$.

The following discussion provides a brief sketch of the proof of Theorem 1 with an eye on intuition. We will then use this as a baseline case with which to compare other specifications of the Colonel Blotto game.

Let P^* denote a feasible n -variate distribution function (i.e., $\text{Supp}(P^*) \in \mathcal{S}$) with the set of univariate marginal distribution functions $\{F_j^*\}_{j=1}^n$ specified in Theorem 1. If player A is using P^* , then player A 's expected payoff under the plurality objective, π_A , when player B chooses any pure strategy $\mathbf{x}_B \in \mathcal{S}$ is

$$\pi_A(P^*, \mathbf{x}_B) = nv - v \sum_{j=1}^n F_j^*(x_{B,j}) \quad (2)$$

recalling that for all j , $F_j^*(x) = \frac{nx}{2}$ for $x \in [0, \frac{2}{n}]$

$$\pi_A(P^*, \mathbf{x}_B) \geq nv - nv \sum_{j=1}^n \frac{x_{B,j}}{2} = \frac{nv}{2}.$$

In a symmetric and constant-sum game that sums to nv , this is sufficient to prove that uniform univariate marginal distributions are optimal.

Before moving on to the case of heterogeneous contests, it is instructive to provide an n -variate distribution function P^* that satisfies the condition that $\text{Supp}(P^*) \in \mathcal{S}$ and has the set of univariate marginal distribution functions $\{F_j^*\}_{j=1}^n$ specified in Theorem 1. The following section provides the construction for such a distribution function. The construction given below can also be extended to cover the case of the symmetric players and heterogeneous contests as in Theorem 2. However, the case of asymmetric players (with either homogeneous or heterogeneous contests), as in Theorem 3, requires a different approach (see Roberson [29] for further details).

Equilibrium Joint Distributions. We now examine the construction of a joint distribution function, which satisfies the properties listed in Theorem 1. Gross and Wagner [6] examine several different constructions of sufficient joint distribution functions (including a fractal construction). The solution that we focus on here extends Borel and Ville's [33] disk solution for the case of three homogeneous contests to allow for any arbitrary finite number n of component contests. This generalized-disk solution exploits the following two properties of regular n -gons: (i) the sum of the perpendiculars from any point in a regular n -gon to the sides of the regular n -gon is equal to n times the inradius, and (ii) letting s be the side length and r be the inradius,

$$s = 2r \tan \frac{\pi}{n}$$

for all regular n -gons.

This outline of the generalized-disk solution follows along the lines of Laslier [26]. Let Ω be the incenter of a regular n -gon with sides of length $(2/n) \tan(\pi/n)$. The inradius is, thus, $(1/n)$. Let S be the sphere of radius $(1/n)$ centered at Ω . Let M be a point randomly chosen from the surface of S , according to the uniform distribution on the surface of

Figure 1. Generalized disk solution for $n = 4$.

S . Let M' be the projection of M on the plane that contains the regular n -gon. Let x_i be the perpendicular from side i to the point M' . For $n = 4$, the generalized disk is shown in Fig. 1.

The surface area of a spherical cap of S with height h is $2\pi rh$. Let $\text{Cap}(i, h)$ denote the spherical cap on S with height h as measured from side i of the regular n -gon. Thus,

$$\begin{aligned} \Pr[x_i \leq h] &= \Pr[M \in \text{Cap}(i, h)] \\ &= \frac{\text{Area}[\text{Cap}(i, h)]}{\text{Area}[S]} = \frac{2\pi rh}{4\pi r^2} = \frac{h}{2r}. \end{aligned}$$

Because the radius $r = (1/n)$, each x_i is uniformly distributed on the interval 0 to $\frac{2}{n}$.

Note that Gross and Wagner's [6] use of regular n -gons places severe restrictions on the supports of the resulting n -variate distributions, and the supports of the resulting joint distributions are contained in a strict subset of the intersection of the n -box $[0, \frac{2}{n}]^n$ and $\mathcal{S}$. For example with $n = 4$, each univariate marginal distribution randomizes continuously on $[0, \frac{1}{2}]$ such that at each point in the support, $x_1 + x_3 = \frac{1}{2}$ and $x_2 + x_4 = \frac{1}{2}$. More generally, for all n , the generalized-disk solution possesses the property that each n -tuple in its support is entirely determined by any two x_i that are not opposite to each other.

Symmetric Players and Heterogeneous Contests

Consider now the case of symmetric players' and heterogeneous contests. If any component contest j satisfies the property that $v_j \geq \sum_{k \neq j} v_k$, then the unique pure-strategy equilibrium trivially involves each player allocating all of their resources to the contest

with the maximal value. But if $v_j < \sum_{k \neq j} v_k$ for all j , then there is no pure-strategy equilibrium. Theorem 2 provides the modification of Theorem 1 that applies in this case. This result is due to Gross [34] (see also Laslier [26]).

Theorem 2 [Gross [34]]. *If $v_j < \sum_{k \neq j} v_k$ for all j , then the pair of n -variate distribution functions P_A^* and P_B^* constitute a Nash equilibrium of the symmetric Colonel Blotto game with heterogeneous contests if they satisfy the following two conditions: (i) For each player i , $\text{Supp}(P_i^*) \subset S$ and (ii) P_i^* , $i = A, B$, provides the corresponding set of univariate marginal distribution functions $\{F_{i,j}^*\}_{j=1}^n$ outlined below.*

$$\forall j \in \{1, \dots, n\}, \quad F_{i,j}^*(x) = \frac{\frac{x}{2v_j}}{\sum_{k=1}^n v_k},$$

$$\text{for } x \in \left[0, \frac{2v_j}{\sum_{k=1}^n v_k} \right].$$

There exist such strategies, and in equilibrium each player's expected payoff is $(1/2) \sum_{j=1}^n v_j$.

For the proof of the existence of a joint distribution which satisfies the conditions of Theorem 2, see Laslier [26] or Gross [34], both of which extend the generalized-disk solution to allow for the differing values of the heterogeneous contests. To see that a pair of distributions of resources, which satisfy the conditions of Theorem 2, form an equilibrium, observe that if player A is using such a P_A^* , then player A 's expected payoff, π_A , when player B chooses any pure strategy $\mathbf{x}_B \in S$ is

$$\pi_A(P_A^*, \mathbf{x}_B) = \sum_{j=1}^n v_j - \sum_{j=1}^n v_j F_{A,j}^*(x_{B,j}) \quad (3)$$

inserting $F_{A,j}^*(x_{B,j})$ from the statement of Theorem 2

$$\begin{aligned} \pi_A(P^*, \mathbf{x}') &\geq \sum_{j=1}^n v_j - \left(\sum_{j=1}^n v_j \right) \sum_{k=1}^n \frac{x_{B,j}}{2} \\ &= \frac{\sum_{j=1}^n v_j}{2}. \end{aligned}$$

Thus, such uniform univariate marginal distributions are optimal.

Asymmetric Players

We now examine the case of asymmetric players ($\beta < 1$). Note that if the strong player (A) has sufficient resources to outbid the weaker player's (B 's) maximal resource allocation β on all n contests (i.e., if $1 \geq n\beta$) then there, trivially, exists a pure-strategy equilibrium, and the strong player (A) wins all of the contests. It is well known that for the remaining parameter configurations, $(1/n) < \beta \leq 1$, there is no pure-strategy equilibrium for this class of games.

The earliest attempt at the asymmetric game is by Friedman [17], who simplifies the game by assuming that for each player i a strategy is a set of one-dimensional marginal distribution functions $\{F_{i,j}\}_{j=1}^n$ that satisfies the condition that the budget holds in expectation ($\sum_{j=1}^n \int_0^\infty x dF_{A,j} = 1$ and $\sum_{j=1}^n \int_0^\infty x dF_{B,j} = \beta$ for players A and B respectively). However, because Friedman [17] focuses on only sets of univariate marginal distributions that satisfy the budget in expectation, this analysis leaves open the question of whether—in the original specification of the asymmetric game—the constraint on the support of the joint distribution function (i.e., that the budget is satisfied with probability one) imposes restrictions on the feasible sets of univariate marginal distributions. These issues are resolved in Roberson [29], which solves the asymmetric game at the level of the n -variate distribution functions. For a large range of parameter configurations, Roberson [29] shows that the constraint on the support of the joint distribution function is, in fact, binding. In such cases the univariate marginal distributions given by Friedman [17] do not arise in equilibrium.

For the sake of brevity we will only examine the case of $n \geq 3$ and $\beta \in ((2/n), 1]$. This corresponds to the portion of the parameter space in which the univariate marginal distributions given by Friedman [17] do arise in equilibrium. See Roberson [29] for the remaining case, $n \geq 3$ and $\beta \leq (2/n)$, in which this relationship breaks down. For the case of $n = 2$, Gross and Wagner [6] provide an equilibrium and Macdonnel and Mastronardi [28] provide the complete characterization of the equilibrium joint distributions. Moving from $n = 2$ to $n \geq 3$ greatly enlarges the set of feasible distributions of resources, and for $n = 2$, the equilibrium strategies are qualitatively different from the $n \geq 3$ case. Theorem 3 summarizes Roberson's [29] characterization of equilibrium in the Colonel Blotto game for $n \geq 3$ and $\beta \in ((2/n), 1]$.

Theorem 3 [Roberson 29]]. *If $n \geq 3$ and $\beta \in ((2/n), 1]$, then the pair of n -variate distribution functions P_A^* and P_B^* constitute a Nash equilibrium of the Colonel Blotto game if and only if they satisfy the following two conditions: (1) For each player i , $\text{Supp}(P_i^*) \subset S_i$ and (2) P_i^* , $i = A, B$, provides the corresponding unique set of univariate marginal distribution functions $\{F_{i,j}^*\}_{j=1}^n$ outlined below.*

$$\begin{aligned} \forall j \in \{1, \dots, n\}, \quad F_{B,j}^*(x) &= (1 - \beta) + \frac{x\beta}{n}, \\ &\text{for } x \in [0, \frac{2}{n}]. \\ \forall j \in \{1, \dots, n\}, \quad F_{A,j}^*(x) &= \frac{x}{2}, \\ &\text{for } x \in [0, \frac{2}{n}]. \end{aligned}$$

Moreover, such strategies exist, and in any Nash equilibrium the expected payoff of the weak player (B) is $\beta(nv/2)$ and the expected payoff of the strong player (A) is $nv - \beta(nv/2)$.

A major part of the proof of Theorem 3 involves showing that there exist strategies that satisfy the two conditions specified above. To do this, Roberson [29] makes a break from the classical constructions, which exploit properties of n -gons, and

provide an entirely new approach.⁵ Since the appearance of the classical solutions to the symmetric case, it had been an open question whether uniform univariate marginal distributions were a necessary condition for equilibrium.⁶ Roberson [29] shows that—as long as the level of symmetry (as measured by the ratio of the players' resource constraints) is above a threshold—there exists a unique set of univariate marginal distribution functions for each player and these involve uniform marginals. Note also that when the players have asymmetric resource constraints, the disadvantaged player optimally uses a “guerrilla warfare” strategy, which involves the stochastic allocation of zero resources to a subset of the component contests. Conversely, the player with the larger budget plays a “stochastic complete coverage” strategy that with probability one, stochastically allocates a strictly positive level of resources to each of the component contests.

For all configurations of the asymmetric Colonel Blotto game, Roberson [29] provides the characterization of the unique equilibrium expected payoffs.⁷ These expected payoffs are illustrated in Fig. 2, as a function of the ratio of the players' resource constraints (β). These payoffs are for the case of at least three-component contests ($n \geq 3$) with a value of $v = (1/n)$ each and player B being the disadvantaged player ($\beta \leq 1$).

Although Roberson [29] focuses on the case of homogenous contests, it is straightforward to extend that analysis to allow for heterogeneous contests, as long as for each distinct contest valuation there are at least three contests with that valuation.

VARIATIONS AND EXTENSIONS

In what follows, we provide a brief overview of several of the directions in which the Colonel

⁵See also Weinstein [32], which provides a related construction in the case of the symmetric Colonel Blotto game.

⁶See, for example, Gross and Wagner [6] and Laslier and Picard [27], which discuss this issue.

⁷Note that uniqueness of the equilibrium expected payoffs follows immediately from the fact that the Colonel Blotto game is constant sum.

Figure 2. Colonel Blotto game payoffs.

Blotto game has been extended and provide directions for future work in this area.

The Majoritarian Objective

The majoritarian Colonel Blotto game is largely an open question. In the case of three contests, symmetric players, and homogeneous contests, the majority objective game is strategically equivalent to the plurality objective game. Therefore, the case of Theorem 1 with $n = 3$ applies directly (see Kovenock and Roberson [3] for further details). The case of three contests, symmetric players, and heterogeneous contests is addressed by Laslier [35], who shows that (as long as $v_j < \sum_{k \neq j} v_k$) the case of Theorem 1 with $n = 3$ applies directly. Observe that this differs from Theorem 2, the corresponding heterogeneous contest game with the plurality objective. That is, in the case of symmetric players and three heterogeneous contests, the equilibrium in the majoritarian game involves each contest receiving the same average resource allocation, while the equilibrium in the plurality game involves the contests with higher valuations receiving higher average resource allocations.

In the case of three contests and asymmetric resource constraints, Weinstein [32] provides bounds on the equilibrium payoffs. But beyond the case of three contests, little is known about the majoritarian Colonel Blotto game.

A Nonconstant-Sum Formulation

In the Colonel Blotto game, each player has a resource constraint and resources are “use-it-or-lose-it” in the sense that any unused resources have no value. There are a number of applications in which unused resources may have positive value. This issue was first examined by Szentes and Rosenthal [36] who examine, among other things, a nonconstant-sum formulation of the majoritarian Colonel Blotto game with three contests and symmetric players.⁸ The equilibrium in this extension is quite different from the constant-sum majority game, and we refer the interested reader to Szentes and Rosenthal [36] for further details. As with the case of the constant-sum formulation of the majoritarian Colonel Blotto game with symmetric players, the case of $n > 3$ is unresolved.

Kvasov [25] examines a nonconstant-sum formulation of the plurality Colonel Blotto game with symmetric players, and Roberson and Kvasov [31] examine the corresponding asymmetric game. The key insight from this variation of the Colonel Blotto game is that—as long as the level of asymmetry between the players’ budgets is below a threshold—there exists a one-to-one mapping from the unique set of equilibrium

⁸In this game the players do not face a budget constraint.

univariate marginal distribution functions in the constant-sum game to those in the nonconstant-sum game. That is, the key features of the equilibrium in the Colonel Blotto game are robust to the relaxation of the “use-it-or-lose-it” feature.

A Continuum of Contests

Myerson [37] introduces a Blotto-type game with a continuum of homogeneous contests, and symmetric players each with the plurality objective. In this game, a feasible distribution of resources is a univariate probability distribution that exhausts the budget in expectation, and the support of which is contained in $\mathbb{R}_+$. Instead of drawing an n -tuple from a joint distribution, the distribution of resources specifies a measure, over any interval of $\mathbb{R}_+$, that corresponds to the proportion of the component contests receiving an allocation of resources in that interval. Myerson [37] applies this Blotto-type game to political parties competing for vote share by simultaneously announcing binding commitments as to how they will allocate a fixed budget across a continuum of voters. Each voter votes for the party offering the highest level of utility, and each party’s payoff is the fraction of votes received by that party. This particular formulation of the redistributive politics model⁹ has been used to study the inequality created by political competition [37], incentives for generating budget deficits [42], inefficiency of public good provision [43,44], campaign spending regulation [45], redistributive competition in an electorate with heterogeneous party preferences [23], inefficient redistributive politics [24], and distortionary taxation [46].

Restrictions on the Strategy Space

Restrictions to the strategy space are an important area for future work on the Colonel Blotto game. Hart [22] provides a complete

characterization of the discrete version of the plurality Colonel Blotto game (with both symmetric and asymmetric players and homogeneous contests). In the case that the players are restricted to choosing only integer amounts of the resource to allocate to each contest, the main features of the equilibria are similar in spirit to those arising in the continuous game. For example, the weaker player utilizes a stochastic guerrilla warfare strategy and the stronger player utilizes a stochastic complete coverage strategy. In addition, the upper bounds of the supports of the univariate marginal distributions are the same in both the discrete and the continuous formulations.

Closely related to the discrete version of the Colonel Blotto game is the restriction to the strategy space examined by Arad [47], which places a further restriction on the set of integer allocations. In particular, that paper considers the case of four component contests and symmetric players with a budget of 10 units of resources who must choose a permutation of the numbers (1, 2, 3, 4).

Alternative Objectives

Although most of the work on multidimensional strategic resource allocation has focused on only the plurality and majoritarian objectives, there are a number of other relevant objectives. Golman and Page [21] examine a variation of the plurality game, which allows for the players to value not only isolated fronts, but also pairs of fronts and even all sets of fronts. In several of these games, pure-strategy equilibria are found to exist. Szentes and Rosenthal [48] examine a variation of the majoritarian game in which winning the overall game requires winning the supermajority of all but one of the component contests. That paper provides an equilibrium in the case that there are a sufficient number of players (strictly greater than two). Except for the case of three-component contests, the two-player case is unresolved.

CONCLUSION

As an exercise in both abstract and applied game-theoretic analysis, the Colonel Blotto

⁹There are several other variations of the redistributive politics model. See, for example, the literature in Cox and McCubbins [38], Lindbeck and Weibull [39], Dixit and Londregan [40], and Dixit and Londregan [41].

game provides a unified theoretical framework that facilitates new ways of thinking about the foundations of optimal resource allocation. This article (i) provides a brief outline of some of the main results on the classic Colonel Blotto game, (ii) surveys several of the theoretical extensions of this framework, and (iii) provides direction for future work in this area.

ALTERNATING RENEWAL PROCESSES

NILAY TANIK ARGON
Department of Statistics and
Operations Research,
University of North Carolina,
Chapel Hill, North Carolina

Consider a stochastic process $\{Z(t), t \geq 0\}$ that alternates between two states—"up" and "down." Assume that at time zero, it is in state "up" and it stays there for a random amount of time (denoted by U_1) before it moves to state "down." After a sojourn of random duration (denoted by D_1) in the "down" state, it moves back to state "up." This cycle repeats indefinitely. Let U_n and D_n denote the time spent in states "up" and "down," respectively, during the n th cycle. If $\{(U_n, D_n), n \geq 1\}$ is a sequence of independent and identically distributed (i.i.d.) bivariate random variables, then $\{Z(t), t \geq 0\}$ is called an *alternating renewal process*. Note that for an alternating renewal process, the "up times" and "down times" of different cycles should be independent from one another. However, within the same cycle, the time spent in the "up" and "down" states could be dependent.

In the following, we assume that $U_n + D_n$ is an aperiodic random variable with cumulative distribution function $F(x)$. (A random variable X is called a *periodic random variable*, if it only takes on integral multiples of some nonnegative number d ; it is called an *aperiodic random variable* otherwise.) We first present the renewal-type equations for alternating renewal processes that arise by conditioning on $U_1 + D_1$. These equations have the following form:

$$H(t) = D(t) + \int_0^t H(t-x) dF(x), \quad t \geq 0, \quad (1)$$

where $D(t)$ is a known function and $H(t)$ is to be determined. These equations are

particularly useful in obtaining $\lim_{t \rightarrow \infty} H(t)$ by applying the key renewal theorem.

We next present, perhaps, the most important result for alternating renewal processes. This result provides the limiting distribution of $\{Z(t), t \geq 0\}$ and can be proved by applying the key renewal theorem to a renewal-type equation in the form of Equation (1).

Theorem 1. *If $\mathbb{E}[U_1 + D_1] < \infty$, then we have*

$$\lim_{t \rightarrow \infty} \Pr\{Z(t) \text{ is in state "up"}\} = \frac{\mathbb{E}[U_1]}{\mathbb{E}[U_1] + \mathbb{E}[D_1]}.$$

For a proof of this result and the case where $U_n + D_n$ is periodic, the reader is referred to Section 8.8 in Kulkarni [1]. In the remainder of this article, we illustrate the various uses of alternating renewal processes and Theorem 1 with two examples.

Example 1. Suppose that $\{N(t), t \geq 0\}$ is a renewal process with an i.i.d. sequence of aperiodic interrenewal times $\{X_n, n \geq 1\}$ having mean $\tau > 0$ and distribution $G(\cdot)$. Let $C(t) = X_{N(t)+1}$ be the length of the interrenewal time that contains t for some $t \geq 0$. ($C(t)$ is sometimes called the *total life* at time t .) We will obtain the limiting distribution of $C(t)$ (as $t \rightarrow \infty$) by defining an embedded alternating renewal process. For fixed $x > 0$, let

$$Z(t) = \begin{cases} \text{up;} & \text{if } C(t) > x, \\ \text{down;} & \text{if } C(t) \leq x. \end{cases}$$

Then $\{Z(t), t \geq 0\}$ is an alternating renewal process with

$$U_n = \begin{cases} X_n; & \text{if } X_n > x, \\ 0; & \text{otherwise;} \end{cases} \quad (2)$$

and

$$D_n = X_n - U_n. \quad (3)$$

Note that $\{(U_n, D_n), n \geq 1\}$ is a sequence of i.i.d. bivariate random variables, where U_n and D_n are dependent for a given n . Using Equations (2) and (3), we get

$$\mathbb{E}[U_n] = \int_x^\infty u \, dG(u)$$

and $\mathbb{E}[U_n + D_n] = \tau$ for all $n \geq 1$. Now applying Theorem 1, we obtain the limiting distribution of $C(t)$ as

$$\begin{aligned} \lim_{t \rightarrow \infty} \Pr\{C(t) > x\} &= \lim_{t \rightarrow \infty} \Pr\{Z(t) = \text{"up"}\} \\ &= \frac{1}{\tau} \int_x^\infty u \, dG(u). \end{aligned}$$

Note that for any $x > 0$, we have

$$\begin{aligned} \frac{1}{\tau} \int_x^\infty u \, dG(u) &= \frac{\mathbb{E}[X_1 | X_1 > x]}{\mathbb{E}[X_1]} \\ &\times \Pr\{X_1 > x\} \geq \Pr\{X_1 > x\}. \end{aligned}$$

This means that for large t , the interrenewal time containing t is stochastically larger than an arbitrarily picked interrenewal time. This result, which may sound counterintuitive at first, is known as the *inspection paradox*. To understand this paradox, suppose that we choose a t at random, where any t is equally likely to be picked. Then, the probability that the selected t lands in a particular interrenewal time must be proportional to the length of that interval. Hence, the interrenewal time where t falls into is expected to be larger than a generic interrenewal time in some stochastic sense.

Example 2. Consider a queueing system with a single server and Poisson arrivals with rate λ . The queue capacity is $K < \infty$, that is, an arriving customer finding K customers in the queue will be lost. In this queueing system, the service is given in bulk to a group of exactly K customers. More specifically, the server does not start service if there are fewer than K customers waiting; when the number waiting reaches K , all K customers are taken into service and administered service collectively. The service time for the group taken into service at the n th service cycle is denoted by X_n , which is an i.i.d. random variable with mean τ and distribution $G(\cdot)$. We will obtain the limiting probability that the server is busy for this queueing system. We first identify a suitable alternating renewal process. For $t \geq 0$, define

$$Z(t) = \begin{cases} \text{up}; & \text{if the server is busy at time } t, \\ \text{down}; & \text{otherwise.} \end{cases}$$

Assume that at time zero, the server has just started a new service. Then $\{Z(t), t \geq 0\}$ is an alternating renewal process with $U_n = X_n$ and

$$D_n = \begin{cases} \sum_{i=1}^{K-k} Y_i; & \text{if there are } k \text{ arrivals} \\ & \text{during the } n\text{th service cycle for} \\ & k = 0, 1, \dots, K-1, \\ 0; & \text{if there are } K \text{ or more arrivals} \\ & \text{during the } n\text{th service cycle,} \end{cases}$$

where Y_i 's are i.i.d. exponential random variables with rate λ . It is clear from above that the n th down time D_n depends on the n th up time U_n and that $\{(U_n, D_n), n \geq 1\}$ is a sequence of i.i.d. bivariate random variables. We next obtain the mean down time. Let B_n be the random variable denoting the number of arrivals during the n th service cycle (or up time). Then, by conditioning on the service time, for all $k \geq 0$ and $n \geq 1$, we obtain

$$\Pr\{B_n = k\} = \int_0^\infty \frac{e^{-\lambda u} (\lambda u)^k}{k!} dG(u).$$

We next condition on the number of arrivals during an up time and obtain the mean down time as

$$\begin{aligned} \mathbb{E}[D_1] &= \sum_{k=0}^\infty \mathbb{E}[D_1 | B_1 = k] \Pr\{B_1 = k\} \\ &= \frac{1}{\lambda} \sum_{k=0}^{K-1} (K-k) \Pr\{B_1 = k\} \\ &= \frac{1}{\lambda} \sum_{k=0}^{K-1} \frac{K-k}{k!} \int_0^\infty e^{-\lambda u} (\lambda u)^k dG(u). \end{aligned}$$

Now, using the fact that $\mathbb{E}[U_1] = \tau$ and applying Theorem 1, we get

$$\begin{aligned} \lim_{t \rightarrow \infty} \Pr\{\text{server is busy at time } t\} &= \frac{\lambda \tau}{\lambda \tau + \sum_{k=0}^{K-1} \frac{K-k}{k!} \int_0^\infty e^{-\lambda u} (\lambda u)^k dG(u)}. \end{aligned}$$

For further examples on alternating renewal processes, the interested reader is referred to textbooks on stochastic processes such as those by Kulkarni [1], Ross [2], and Tijms [3]. For further applications in reliability systems, see Aven and Jensen [4].

AMERICAN FOOTBALL: RULES AND RESEARCH

RICK L. WILSON
Oklahoma State University,
Oklahoma City, Oklahoma

AMERICAN FOOTBALL—RULES AND BACKGROUND

The objective of American football is to outscore your opponent, an obviously common feature of many competitive sports. It is a team sport, and often thought as one of the most violent and physical sports. Nonetheless, because of how play has repetitive starts and stops, it has developed into a very strategic game, one in which scientific analysis can be helpful to decision makers, whether it be coaches, players, owners, and so on.

Explaining the game of American football to a novice is a challenge due to the more complex set of rules and the “start and stop” nature of the game, which allows a variety of strategic decisions throughout. For instance, in the game known as *soccer* in the United States, you score a goal by advancing the ball past the opponent’s goalkeeper into the net. There are rules that dictate advancement and play of the game (cannot use your hands and arms to advance the ball, corner kick rules, etc.), but arguably, play is quite straightforward.

The same cannot be said for American football. In general, the objective is to advance the ball into an opponent’s end zone. The ball can be advanced either by running of the football by a player (a running play) or by passing the ball to a teammate (passing play). Points can be scored in a variety of ways. For instance, if the ball is advanced successfully into the opponent’s end zone, a touchdown occurs, and the team scoring the touchdown is awarded six points. There are other ways in which points can be scored (field goals, safeties, extra points, etc.), and they are outlined later in the article.

American football is a timed sport, and the winner is the team with the most points when game time expires. As with other sports, most levels of play now allow for “overtime” in case the game ends in a tie, akin to extra time in “soccer.” This “overtime” process has not always been in place, and as pointed out later, the process differs depending upon what “level” of American football one is playing.

While primarily a US sport, the game is played outside the United States as well. A similar game is played in Canada (Canadian Rules football), while professional and collegiate leagues have existed in Europe and elsewhere. Of note is the attempt by the professional National Football Leagues (NFLs) to globalize interest in the sport by playing select games in Mexico, London, other points in Europe, and so forth.

Both the United States and Canadian version of football have their origins from rugby. Football is played at all age levels, as kids from the United States grow up playing in backyard games and in empty lots in neighborhoods. This tends to become more serious at decidedly younger ages with each passing year, and there are many competitive youth leagues starting from age 5, culminating with the usual teams fielded by the junior high and high school age teams. American football has become immensely popular at the collegiate and professional level, perhaps even surpassing the sport of baseball as “America’s pastime.”

College football tends to be the major revenue producing sport for most major US University athletic departments, and millions of dollars are spent (and earned) on its care and feeding. The NFL is the major professional league in the United States, and the Super Bowl, the championship game of the league played every February, draws millions of viewers from many nations. The Super Bowl is typically the most watched TV event each year. The money spent on attending the games, the popularity of the sport for TV, and how people live their lives around the sport illustrates that American Football has just

as “rabid” fans of any sport around the world. Even college football, where players are not paid to play (they are amateurs by definition), has become a big money operation.

BASIC RULES OF AMERICAN FOOTBALL

Fundamentals

Each team has 11 players on the field at any one time. Because plays start and stop, free substitutions are allowed in between plays. The offense is the team in possession of the ball, and they will try to advance the ball toward its opponent’s end zone. The defense attempts to stop the offense from moving the ball down the field.

At the major levels (college and professional) the game is played on a field that is 100 yd long, not counting the two end zones (each of which is 10 yd long). (Youth leagues may play on slightly smaller dimensions, but even this is getting rarer.) The field is approximately 53.3 yd wide. At the back of the end zones, goal posts are placed in the middle of the field. The goal posts have a crossbar 10 ft high, and have “uprights” on each end of the crossbar. This provides a target for successful field goals and extra points that are attempted via kicking. The goalposts are typically about 18–23 ft apart (depending on the level of play, wider at the younger levels, closer together for the NFL).

Starting the Game

To start the game, a coin toss is held to determine which team gets to go on offense first, and which side of the field a team “defends.” Because the football is thrown and kicked (and it is not particularly aerodynamic), the outside elements (such as the wind) are important aspects to consider in the strategy of the game. The team that wins the coin toss can elect to receive the ball, or choose which side of the field to defend, or defer the choice to the second half. The second team chooses accordingly based upon the first team’s choice. Often this choice is dictated by weather conditions, emotional thoughts of the coaching staff (“Let’s take the ball and ram it down their throats and score right

away!!”), or in the case of deferring, the concept of trying to get the last choice much like the alleged advantage possessed by the home team hitting last in a baseball game.

At the collegiate and professional level, the game is split into four quarters of 15 min each. The first two quarters are referred to as the *first half*, and the second two the *second half*. The team that has the ball at the end of the first quarter retains possession for the start of the second quarter, and likewise for the end of the third quarter, going into the fourth quarter. However, at the end of the first half, possession is not retained, as the start of the third quarter begins with a choice by the team that either deferred at the coin toss or that did not pick its “option” at the beginning of the game.

The game clock stops after certain plays, so it is unlike soccer, which has a continuously running clock. The clock stops when an “incomplete pass” is thrown (described below), when there is a change in who has “possession” of the ball, when a player with the ball runs or is hit out of bounds during the final 2 min of a half, among other reasons. If each team has scored the same number of points at the end of the four quarters (“regulation time”), most levels of play have incorporated an overtime feature that allow additional playing by the teams in attempt to break the tie. The process employed varies by level (e.g., the collegiate overtime process is considerably different than the NFL).

At the start of the game and the start of the second half, and after a team scores, the team “kicks off” to the other team, and the receiving team tries to advance the kickoff by running with the football. When a runner with the ball is tackled, the play is over, the spot where the runner was tackled is marked, and the team with the ball is now on offense.

Note that even when kicking off after scoring, a team can try to recover its own kickoff. This is called an *on-side kick*. A kickoff must travel 10 yd before a member of the kicking team can touch it and try to recover it for themselves. A team might employ this strategy on the kickoff when they are behind late in the game and are trying to quickly make up the deficit. Alternatively, coaches can sometimes use an on-side kick when the

other team is not expecting it for the “surprise” effect.

Running “Plays” from Scrimmage

The location of the ball is called the *line of scrimmage*. Each team must stay on its side of the line of scrimmage before a play is started. The offensive team (the team in possession of the football) has four downs (plays) to advance the ball 10 yd. If they advance the ball at least 10 yd during these plays, they are deemed to have received a “first down,” and then are awarded four more plays, with another “goal” of 10 yd for another first down. If the defense stops the offense from advancing 10 yd in four plays, they (the defensive team) get possession of the ball at the point where the ball was last “downed.” Then, due to the specialization of today’s teams, the offensive specialists for the team that just stopped the other would come out to play, and the team that gave up possession of the ball would bring out its defensive specialists.

A play starts when the offense player called the *center* gives the ball (typically between his legs called a *snap*) to the “quarterback.” The quarterback is somewhat like the field general, and typically handles the ball on every play. The quarterback might hand or lateral (a backward pass) the ball to a running back who will try to advance the ball forward before being tackled (or driven out of bounds). Alternatively, the quarterback might retreat further behind the line of scrimmage and try to throw the ball to a receiver down the field to advance the ball.

If a running back, or anyone who is running the ball, has his knee go down and hit the ground, he is considered tackled, and the next play will start from that point. If a person running the ball loses possession of it, it is a live ball and may be advanced freely by either the offense or the defense . . . so it is possible for a defense to score points as well (say on a fumble return for a “touchdown”).

Similarly, if a pass is thrown and it hits the ground, it is called an *incomplete pass*, and the ball returns to the previous line of scrimmage for the next play. If the offense team catches a pass, then the receiver can

advance the ball until he is tackled. If the defensive team catches the pass, it is called an *interception*. As with a fumble, the defense can advance the intercepted ball toward the other team’s goal line until they are tackled, and they will have possession of the ball at the end of the play.

There is much strategy involved in play calling, both offensively and defensively. Many assistant coaches analyze other team’s tendencies for play calling in various situations, and there exists sophisticated video systems and software to assist in the analysis [e.g., see the Hudl system [1]]. The game has become very specialized and scientific even at this micro level.

Typically, if a team is faced with fourth down and has more than just a yard or two to make a first down, or if it is close to its own goal line (or not close to their opponent’s goal line), it will “punt” the ball away to the other team. Today, punters can routinely kick the ball 50 yd from scrimmage, so this conservative strategy is used to minimize the risk in trying to make a first down and failing; giving the opponent the ball close to its goal line, they might be able to score easily. Of course, the receiving team can advance a punt as well, much like a kickoff. This is yet another case of “conventional coaching wisdom,” where a coach would be considered a high risk taker if they tried to get a first down on fourth down on its “own” side of the field. Given the high pressure of being successful, and the high salary made by most coaches, few are willing to do something that would be viewed as risky or unusual, especially where a single poorly timed failure, counter to conventional wisdom, could lead to the firing of a high profile coach.

Scoring Points in American Football

When a team, by a running play, a passing play, a kickoff return, a punt return, a fumble return, or an interception return crosses its opponent’s goal line in possession of the ball, this is called a *touchdown* and the team earns six points.

After a touchdown, the scoring team then attempts an “extra point.” The ball is placed at the 3-yd line (college) or the 2-yd line

(NFL). Typically, a team will try to score a 1-point extra point by attempting to kick the ball through the aforementioned goalposts. If they are successful, one additional point is awarded, for a total of seven points.

If the team tries to run or pass the ball into the end zone from there, they are awarded two points if they are successful. If they are not successful, they of course score no additional points. This is a more risky choice (typically) than a kicked extra point. Conventional wisdom holds that two-point extra points are successful between 40% and 45% of the time [2]. This number varies in this range each year, and also differs throughout the levels of competitive football.

Note that in both cases, should the defensive team block a kick and advance it all the way down the field into the offensive team's end zone, or likewise return a fumble or interception, the defensive team is awarded two points in both cases. This is a rare occurrence but is worth noting.

Sometimes, when an offensive team decides that they do not want to try to achieve a first down on fourth down, and they are close enough to its opponents end zone, it lines up to attempt a field goal. A field goal is similar to the previously mentioned extra point, except it occurs from a variable (typically further) distance away. If a kicker successfully kicks the ball through the goalposts, the team is awarded three points. Field goal kickers have become very accurate and strong of leg over the last 20 years, and can routinely make a majority of their kicks from 50 yd and less.

Note that if a kicker misses, the other team gains possession of the ball at either the 20-yd line or the previous line of scrimmage, whichever is most advantageous. If an opposing team blocks an attempted field goal, the ball becomes "live" and can be advanced as if it was a fumble.

Finally, a defensive team can score two points for a safety by tackling the offensive team in its own end zone (behind the goal line). This too is a relatively rare occurrence. If a team scores a safety, the other team must execute a "free kick" from the 20-yd line, as the defensive team gets a bonus whereby they receive possession of the ball even after

being awarded the two points for the safety. The same rules apply for the free kick that applies for the kickoff.

Final Comments on American Football Rules

There are many minor differences between college football and professional football (NFL) rules, but many are small issues of such things as how the clock is stopped and started, where "hashmarks" are placed on the field (this impacts the starting point for plays), the width of the goalposts, the definition of when a player is declared tackled, and how penalties are assessed when players are caught in rule infractions, among other "subtle" items. The basic premises, rules, and scoring remain basically the same.

One of the biggest differences between NFL and college football rules are the means for how they deal with games that are tied at the end of the fourth quarter. Both employ overtime, but the NFL uses "sudden death" where the first team that scores wins, while college football uses an overtime process that allows each team an equal number of times where they have the ball ("possessions"). Each approach has been criticized and/or analyzed, and this is one of the areas discussed in this article where research has examined some strategic decisions or processes in American Football.

The next section presents a brief summary of some representative analyses that have been undertaken applying research studies to American Football. This discussion is not meant to be exhaustive nor complete, but provides the reader with an idea on how the rich strategic nature of American Football can be studied using operations research techniques.

EXAMPLES OF RESEARCH IN AMERICAN FOOTBALL—ANALYZING THE CONVENTIONAL COACHING WISDOM

American College Football Overtime

Beginning in 1996, the National Collegiate Athletic Association (NCAA; governing body of major college football) adopted new rules for college football overtime games. Prior to

this time, games were allowed to end in ties. Under these new rules, each team is given one offensive possession starting at the opponent's 25-yd line. The team with the most points after the first overtime period is declared the winner. If the game is tied after the first overtime period, a second period will be played. If the game goes to a third overtime period, and for all subsequent periods, teams are required to attempt a two-point extra point after any touchdown [3].

Before the first overtime period, a coin toss is held. The winner of the coin toss chooses to start on either offense or defense in overtime (they could also opt for end of the field, but this choice is very rare and generally occurs because of weather and/or field conditions). Interestingly, this coin toss determines the possession for all overtime periods, as the team's alternate offense and defense first in each subsequent period that is necessary. Thus, a team that starts on offense in Period 1 will start on offense in every odd-numbered overtime period. This same team would start on defense in Period 2 and all subsequent even-numbered overtime periods.

The overtime method used in college football is designed to be fair to both teams and minimizes the importance of the coin toss. This is in stark contrast to the NFL's sudden death overtime system. In sudden death, the first team that scores wins the game, regardless of whether or not the other team had the opportunity to be on offense (i.e., "has possession of the ball"). This system has long been criticized for favoring the team that gets possession of the ball first, implying that the team that wins the coin toss has an unfair advantage and usually wins the game.

Between the years of 1974 and 2003, 28% of all NFL overtime games ended with the team winning the coin toss getting to go on offense first, scoring, and winning the game without allowing the other team to have the ball. Critics charge that this high percentage demonstrates that the system is unfair to the team that has the misfortune of losing the coin toss [4]. In the most recent NFL season, this number was even more extreme, as Clayton [5] reports that 43.4% of NFL's overtime games during the 2008–2009 season were won in the first possession by the

team that won the coin toss, and that overall, 63% of the overtime winners won the coin toss.

Even though both teams get an offensive possession in college football overtime rules, conventional coaching wisdom dictates that the team that wins the coin toss should start on defense (somewhat like being the home team in baseball, getting the "last at-bat"). Since this conventional wisdom has been practiced in all but four occasions (out of more than 390 games to date), there seems to be an implied advantage to the winner of the coin toss.

Research showed that in college football, there was not a large advantage to being on defense first [3]. Coaches were surveyed, and they thought that teams who started on defense won as much as 75% of the time. The actual figures through 2005 were 56%, and in fact the result was nearly 50% for the years from 2001 to the present. From 2001 through 2003, the team that went first actually won nearly 60% of the time!

The studies found that one interesting factor is the "pressure" of being on defense first and having to match the opponent if they score a touchdown on its first possession (A team that scores a touchdown on its first possession wins approximately 70% of the time). There is evidence that if you are the coach of a good offensive team, or fear that your team is overmatched the longer the overtime periods continue, you might be better-off by breaking tradition and choosing to take the ball first in overtime.

At least college football overtime rules seem fair to both teams. Interestingly, the NFL has again opted not to change its overtime process for the 2009 season, even with the evidence that its overtime process gives an unfair advantage to the coin toss winner. The reason—not enough support from teams, and players who expressed "safety" concerns if current rules were to be changed. Funny, what making hundreds of thousands of dollars per game will do to your competitive spirit.

The Fourth Down Punting Strategy

In the previous description of American Football rules and the typical process of a game,

the concept of punting away the ball on fourth down was discussed. Oftentimes, coaches opt to punt the ball on fourth down and inches rather than to go for a first down due to their cautious nature (why take a chance if it might cause me to lose my million-dollar job?).

Romer [6] studied the specific fourth down punting decision in the NFL and found that conservative decisions made were counter to a maximize wins objective, and estimated that this cost teams at least one win every three years.

Taking this research study to an extreme, Pulaski Academy (Arkansas) High School coach Kevin Kelley [7] has adopted an offensive philosophy where his team never punts—they have not punted for 20 straight games. This past season, they won the 5A State Championship in Arkansas by applying this philosophy. Coach Kelley basically uses a form of expected value calculations in justifying his very nontraditional approach to fourth down, and his results (83% winning percentage during his time there) speak for themselves. Coach Kelley also uses onside kicks as a regular strategy. He also attributes some of his strategy to the output of ZEUS (pigskinrevolution.com), an analytic computer-based tool that studies strategic decision making in the NFL.

Two-Point Conversions and Decision Analysis

In the days before overtime in college football, coaches were oftentimes faced with tough decisions late in the game. When scoring a touchdown late, and trailing by 1, should a coach go for the win, or settle for a tie?

An even more interesting scenario was raised in the classic Janssen and Daniel article [8] on using decision analysis in deciding when to go for a two-point conversion. The game under study was the 1967 Harvard-Cornell game, but it very well could have been the 1969 Arkansas-Texas game (a game of the two top-rated teams at the time), or one of the most famous bowl games of all time, the 1984 Orange Bowl game between Miami (Florida) and Nebraska.

In all of these cases, one team was faced with a 14-point deficit, and scored a touchdown late in the game to bring them within

eight points. Not much time remained, so the best scenario that the team trailing could hope for would be to hold the other team, get the ball back, and then score another touchdown with little or no time remaining in the game. Before overtime, a coach would be interested (one would assume) in trying to maximize the likelihood that his team would win.

Janssen and Daniel discussed the implications and circumstances surrounding Cornell's decision to go for two points after its first touchdown that made the score 14-6. The team opted to go for two points and failed, and when they scored later in the game and failed again at the two-point conversion; it was left with a 14-12 loss, and was criticized for not following conventional wisdom (which would have been to go for the kick after the first touchdown, then do the all-or-nothing two-point conversion after the second touchdown). Janssen and Daniel explain that the conventional wisdom strategy is oftentimes suboptimal and devalues a tie.

Interestingly, coach Darryl Royal of Texas used the optimal strategy in his team's 15-14 victory over Arkansas. Most people recall the gambling fourth down pass that was completed in that game—few recall coach Royal's gutsiness in choosing the arguably "correct" way of executing extra points when Texas scored at the start of the fourth quarter to make it 14-6. Texas went for a two-point extra point, made it, and the score stood at 14-8 when Texas scored late in the game. A simple one-point kick was all Texas needed to win 15-14.

Nebraska's coach Tom Osborne was roundly praised for his decision to go for two late in the 1984 Orange Bowl, when a tie almost assuredly would have given Nebraska the so-called National Championship. Nebraska trailed 31-17 late in the fourth quarter, when they scored to make it 31-23; they then kicked the one-point extra point to make it 31-24. Then, scoring with 47s left, at 31-30, Osborne elected to go for two points; it failed, and Miami won the game, and Osborne won the respect of the nation. Unfortunately, decision analysis indicated that perhaps the better decision was to go for two when it was 31-23!!

THE BOWL CHAMPIONSHIP SERIES (BCS), COMPUTER RATINGS, AND VOTER POLL RESEARCH

College Football—No Play-off?

NCAA Division I-A college football remains the only major US college sport that does not utilize a play-off to determine its champion. There are a variety of reasons for this, not the least of which is money [9].

For years, voter polls determined the so-called “Mythical National Champion.” A quick look through college football history will show many seasons where voter polls disagreed with the “champion.” This phenomenon has seemed to trouble football fans much more during the last 20 years, perhaps due to society’s increased focus on “Who’s No 1?” It is also worth noting for those not familiar with Division I-A football that with nearly 120 teams playing a normal schedule of 12 games each, many teams may have the same record or same number of wins, and their win–loss record has never been solely utilized as a way of awarding the mythical national championship.

A series of controversial endings to the college football season in the late 1980s and early 1990s led influential people in college football to attempt to develop a process in which a single champion could be named. This led to the creation of the Bowl Coalition process, which started in 1992. Unfortunately, not all major collegiate conferences participated in this process, and so split or controversial national champions still occurred in 1993, 1994, and 1997. The continued controversy and the hope for a more robust method for selecting the participants led to the creation of the Bowl Championship Series (BCS) in 1998, which included “objective” measures of team strength by utilizing computer rankings (in addition to voter polls). However, controversy has been the rule rather than the exception since the BCS’s inception, and it has seemingly changed its approach in determining the top two teams each year it has existed. The controversy has been so pervasive that congressional hearings were held during the last few years to discuss the “BCS Mess.”

Team Rankings

The root of the problem is the BCS leadership’s failure to explicitly state criteria for determining the final two teams. Additionally, the mathematical models used in the BCS approach have often come under criticism and scrutiny. There has been a fair amount of research in the academic literature on college football ranking methods that date back many years ago [10]. Most of the published research has focused on how a particular approach would rank teams in a given season, and then argue, using some form of face validity, that one approach is superior to another.

Research continues in a variety of areas related to ranking—a quick scan of the academic literature turns up a number of different recent studies [11–14]. As the BCS and academic researchers continue looking for the holy grail of ranking methodologies, one of the challenges faced is how to objectively determine which ranking method performs best. There appears to be no satisfactory solution to the problem at present, but academic and college football fans keep searching.

Voter Poll Findings

One of the key components of the formula that makes up the BCS calculations is the use of voter polls. Human “experts” (at least expert in theory) rank the football teams. For many years, these rankings have been controversial, and the voters have claimed to possess many biases and inaccuracies. There has been a fair amount of research seeking to validate or invalidate these claims.

A study by Goff [15], validated in part by Lebovic and Sigelman [16], found that there was “path dependence” in voting in the AP voter poll. Thus, a team’s standing at the beginning of the season, when very little actual performance data is known about team strength to drive voter decisions, has a significant impact on the final ranking of the team. This has led some to call for no opinion polls prior to the midway point of the season.

Campbell *et al.* [17] observed the 2003 and 2004 voting polls and found that a team that appeared more on television had bigger adjustments made in its poll standings, all

other things being equal. Logan [18] studied AP voter polls and found some interesting results that countered “conventional wisdom” of voter polls—that it is better to lose later in the season than early, that voters do not pay attention to the strength of the opponent, and that the benefit of winning by a large margin is negligible. Stone [19] also studied the voters and found systematic and statistically significant errors from a Bayesian standpoint. Findings included evidence that voters overreact to losses by higher ranked teams, improve rankings excessively after wins at home, and worsen rankings excessively after large margin losses on the road, especially for higher ranked teams. Decisive wins against unranked teams are unappreciated by voters, as well.

As major college football in the United States seeks to try to sort out the “BCS Mess,” even involving the strategic focus list of new US President Barack Obama, the quantitative research undertaken by operations researchers will continue to play a role in trying to “optimize” the decisions.

MARKET EFFICIENCY AND OTHER ISSUES IN THE NFL BETTING MARKET

Legal or not, betting on sporting events has long held the interest of the general population, and has served as an easily accessible data source for academicians seeking to test financial theories of market efficiency. Research has also been undertaken in public to try to find strategies that can be used to do more than break even in betting. There is a rich history of published research in this area as it is related to American Football.

Stern’s 1991 study [20] that deals with the probability of winning an NFL football game is a great starting point in this area. Stern’s empirically developed premise was that the probability of winning a football game is a random normal variable with a mean equal to the Las Vegas determined betting “point spread” and a standard deviation of 14. The point spread is a surrogate indicator of the difference in team strength but, in practice, it also considers additional

factors. It is well known that Las Vegas casinos set the odds, or point spreads, for football games such that the amount of money bet on each team is approximately equal. As those who accept bets receive a certain percentage of all winning bets (and keep all losing bets), this approach ensures steady Casino profits.

As an example of this premise, consider two teams—Baltimore and New York—and the Vegas odds have chosen Baltimore as a seven-point favorite. Stern’s premise would indicate that Baltimore would have a $Z(7/14) = 0.6914$ or 69.14% chance of winning the game, while New York would have a $1 - 0.6914 = 0.3086$ or 30.86% chance.

Stern’s work has oftentimes been used in trying to determine strength of schedule for teams, even in a ranking context. Other studies have focused more on the wagering issue.

Numerous studies have appeared in the marketing literature that analyze the professional and college football betting markets [21], using an analogy with securities markets. Past research included statistical approaches to test for market efficiencies [22], while others have explored specific betting strategies to determine if they lead to unusual profits. A comprehensive paper by Sapra [23] has recently looked at intraseason efficient and interseason overreaction to the NFL betting market. They also reference a number of the most recent studies in this area. They conclude that point spread by itself indicates the likelihood of victory, and thus the market is efficient. They point out the need for additional research on variations from year to year.

CONCLUSION

This brief article has reviewed the rules and playing process of American football. In the second half of the paper, some relevant research related to college and profession American football has been reviewed. This review is not meant to be comprehensive, or necessarily in depth, but gives the reader an idea of some of the interesting and practical research questions that exist in this domain for fellow operations researchers.

AN INTRODUCTION TO LINEAR PROGRAMMING

JAMES J. COCHRAN
Department of Marketing and
Analysis, College of Business,
Louisiana Tech University,
Ruston, Louisiana

A PRELIMINARY OVERVIEW OF OPTIMIZATION

At its most elemental level, optimization refers to the identification of the best element(s) from a domain (or allowable set of available alternatives) with respect to the application of some function to these elements. The unknown values of these elements are referred to as *decision variables*, the set of available alternatives (i.e., collection of values of the decision variables that may be considered) is referred to as the *feasible set*, the function used to evaluate the relative performance of these elements is referred to as the *objective function*, and the coefficients and exponents that operate on the decision variables in the objective function are referred to as *parameters*. An element from the feasible set that generates the optimal value with respect to the objective function is called an *optimal solution*.

In the simplest case of optimization, one seeks to minimize or maximize a real objective function through systematic evaluation of this function for values of real variables that belong to the feasible set. The systematic approach used to identify various elements of the feasible set, evaluate the objective function for these various elements of the feasible set, and find an optimal solution is referred to as a *solution algorithm*.

Depending on the characteristics of the optimization problem, a solution algorithm for a class of optimization problems may identify either a global or local optimal solution. A *global optimal solution* is optimal over the

entire feasible set, while a *local optimal solution* is optimal over a subset (or local neighborhood) of the feasible set. Some optimization problems have more than one global optimal solution; in such cases, these solutions are referred to as *alternative optima*. Ideally, a solution algorithm will identify and confirm a global optimal solution(s) for a problem in a reasonably short period of time.

These concepts combine to form the basis of optimization theory, which is an important area of application and research in operations research. Optimization plays an important role in many areas of application including manufacturing and production; finance and investing; engineering; marketing, logistics, transportation, distribution, and supply-chain management; network design; and telecommunications.

UNCONSTRAINED VERSUS CONSTRAINED OPTIMIZATION

Optimization problems may be classified as *unconstrained* or *constrained*. An unconstrained maximization problem is defined as

find $\mathbf{X}^* = \operatorname{argmax}_{\mathbf{X}} f(\mathbf{X})$ where $f: \mathbb{R}_n \rightarrow \mathbb{R}$,

where

$\mathbf{X}$ is an element of n -dimensional real space;

$f(\cdot)$ is the objective function that maps an n -dimensional element onto the set of real numbers.

An unconstrained minimization problem is defined similarly through the use of the *argmin* function. In unconstrained optimization problems, no restrictions are placed on the potential solutions $\mathbf{X}$ (see ***Methods for Large-Scale Unconstrained Optimization*** for a technical discussion of unconstrained optimization).

In constrained optimization, one is again attempting to identify a best element from the feasible set with respect to the objective

function. However, instead of searching over all elements in n -dimensional real space (as is done in unconstrained optimization), the search is now limited to a predefined subset of the n -dimensional real space.

Constrained optimization problems can be represented in the following manner:

$$\begin{aligned} \text{find } \mathbf{X}^* \in \operatorname{argmax}_{\mathbf{X} \in \mathbf{A}_n} f(\mathbf{X}) \\ \text{where } f : \mathbf{A}_n \rightarrow \mathbb{R} \text{ and } \mathbf{A}_n \subset \mathbb{R}_n, \end{aligned}$$

where $\mathbf{A}_n$ is the predefined feasible space containing all values of $\mathbf{X}$ that satisfy all limitations that have been imposed on values of the decision variables.

The limitations that are imposed on values of the decision variables are referred to as *constraints*. If the objective function and all constraints are linear with respect to the decision variables, the problem is a *linear programming* problem.

A SIMPLE LINEAR PROGRAMMING EXAMPLE

The process of taking information from a real situation and representing it symbolically is referred to as *mathematical modeling* or *problem formulation*. Consider the following simple example:

Suppose a producer of single serve packets of powdered fruit drink mixes wants to decide how much of two products, *Zesty Lemon* and *Super Zesty Lemon*, to produce on a given day. Each of these products consists of only two ingredients (sugar and powdered lemon juice); a single serve packet of *Zesty Lemon* contains two ounces of sugar and one ounce of powdered lemon juice, while a single serve packet of *Super Zesty Lemon* contains two ounces of sugar and two ounces of powdered lemon juice. Eight hundred ounces of sugar and six hundred ounces of powdered lemon juice are available for daily production of *Zesty Lemon* and *Super Zesty Lemon*. An ounce of sugar costs the producer 3¢ and an ounce of powdered lemon juice costs the producer 5¢, and the producer can sell packets of *Zesty Lemon* and *Super Zesty Lemon* for 21¢ and 32¢, respectively. How many packets of *Zesty Lemon* and *Super Zesty Lemon* powdered drink mix should the producer make on a daily basis in order to maximize profit?

In this problem the goal is to maximize profit, and the decision variables (unknown values that will ultimately determine how well this goal is met) are the number of packets of *Zesty Lemon* and *Super Zesty Lemon* powdered drink mix to produce. To facilitate the formulation of this problem, arbitrarily designate the decision variables as X_1 (the number of packets of *Zesty Lemon* to produce) and X_2 (the number of packets of *Super Zesty Lemon* to produce).

A packet of *Zesty Lemon* powdered drink mix sells for 21¢ and uses 2 ounces of sugar (each of which costs 3¢) and 1 ounce of powdered lemon juice (which costs 5¢). This information can be used to determine that the profit per packet of *Zesty Lemon* powdered drink mix is

$$21¢ - [2(3¢) + 1(5¢)] = 10¢.$$

Similarly, since a packet of *Super Zesty Lemon* powdered drink mix sells for 32¢ and uses 2 ounces of sugar (each of which costs 3¢) and 2 ounces of powdered lemon juice (each of which costs 5¢), the profit per packet of *Super Zesty Lemon* powdered drink mix is

$$32¢ - [2(3¢) + 2(5¢)] = 16¢.$$

Thus, the profit the producer will earn can be stated functionally (in cents) as

$$10X_1 + 16X_2,$$

and the objective function of this problem (in cents) is

$$\text{Maximize } 10X_1 + 16X_2.$$

The coefficients applied to the decision variables in the objective function are called the *objective function coefficients*. In this problem, 10 is the objective function coefficient for *Zesty Lemon* powdered drink mix and 16 is the objective function coefficient for *Super Zesty Lemon* powdered drink mix.

If this were a complete statement of the problem, the manufacturer could produce an unlimited amount of *Zesty Lemon* and *Super Zesty Lemon* powdered drink mixes and generate an infinite profit. However, limitations

on the amount of sugar and powdered lemon juice available for production prevent the producer from pursuing this strategy.

The producer has 800 ounces of sugar available, and it takes 2 ounces of sugar to make a single serve packet of *Zesty Lemon* and 2 ounces of sugar to make single serve packet of *Super Zesty Lemon*. Since the producer cannot use more than the 800 ounces of sugar available in the daily production, this implies the following limitation:

$$2X_1 + 2X_2 \leq 800.$$

The coefficients applied to the decision variables in a constraint are called *constraint coefficients*, and the value on the right side of the inequality is called the *right hand side value* of the constraint. In this constraint, the expression on the left hand side of the inequality represents the total ounces of sugar used in the daily production and the value on the right hand side of the inequality represents the ounces of sugar available.

The producer also has 600 ounces of powdered lemon juice available, and it takes 1 ounce of powdered lemon juice to make a single serve packet of *Zesty Lemon* and 2 ounces of powdered lemon juice to make a single serve packet of *Super Zesty Lemon*. The producer cannot use more than 600 ounces of powdered lemon juice in the daily production, and this implies the following limitation:

$$X_1 + 2X_2 \leq 600.$$

In this constraint, the expression on the left hand side of the inequality represents the total ounces of powdered lemon juice used in the daily production and the value on the right hand side of the inequality represents the ounces of powdered lemon juice available.

These two constraints represent limits on values of the decision variables (the number of packets of *Zesty Lemon* and *Super Zesty Lemon* powdered drink mix to produce). Note also that it is impossible to produce a negative number of packets of either *Zesty Lemon* or *Super Zesty Lemon* powdered drink mix. These limitations, which are referred to as *nonnegativity constraints*, can be stated in

the following manner

$$X_1 \geq 0.$$

$$X_2 \geq 0.$$

The nonnegativity constraints combine with the constraints on available ounces of sugar and powdered lemon juice to define the feasible region A_n , and the complete problem formulation is

$$\text{Maximize } 10X_1 + 16X_2.$$

$$\text{subject to } 2X_1 + 2X_2 \leq 800$$

$$X_1 + 2X_2 \leq 600$$

$$X_1 \geq 0$$

$$X_2 \geq 0.$$

This simple example is provided for illustrative purposes; real applications of linear programming can (and often do) encompass millions of decision variables and constraints [1]. Also note that the relationship between the left and right hand sides of a constraint may be less than or equal to ($\leq$), greater than or equal to ($\geq$), or equal ($=$); constraints that feature strict inequality relationships ($<$ or $>$) between the left and right hand sides are typically avoided. Finally note that in the expressions that represent the constraints, all decision variables have been placed on the left side and all constants have been placed on the right side; although not necessary, this format generally facilitates understanding of the model and will be utilized throughout this discussion.

LINEAR PROGRAMMING ASSUMPTIONS

Four conditions must be met in order for a linear programming formulation to provide an appropriate representation of a problem scenario. These conditions are as follows:

- *Additivity.* *Nonlinear interactions* between decision variables cannot occur. The contribution made by any decision variable to the objective function must be independent of the values of all other decision variables.

Furthermore, the contribution made by any decision variable to the left hand side of each constraint must be independent of the values of all other decision variables.

- *Proportionality.* Relationships must be *linear*. The contribution made by a decision variable to the objective function must be proportional to the value of the decision variable. Furthermore, the contribution made by a decision variable to the left hand side of each constraint must be proportional to the value of the decision variable.
- *Divisibility.* Decision variables must be permitted to take on any value in a continuous range.
- *Deterministic Nature.* The value of each parameter (i.e., each objective function coefficient, constraint coefficient, and right hand side value) must be known with certainty.

Alternative approaches for modeling problems that do not meet these conditions have been developed. For example, problems that violate the additivity and/or proportionality assumptions may be modeled using *nonlinear programming*.

Problems that violate the divisibility assumption may be modeled with *integer programming*. Such problems may be designated as *integer* (all decision variables are restricted to integer values) or *mixed integer* (a subset of the decision variables are restricted to integer values). Combinatorial optimization problems generally fall into the category of integer programming problems.

Problems that violate the deterministic nature assumption can be modeled with *stochastic programming* (when the probability distributions associated with the values of the unknown parameters are known) or *sample-based programming* (when sample data is used to estimate the values of the unknown parameters). *Robust programming* and *fuzzy programming* are other approaches to dealing with uncertainty in the values of the parameters.

In addition, problems that have several inherent goals can be modeled with *goal*

programming, and problems for which only a subset of constraints must be satisfied can be modeled with *disjunctive programming*. For detailed discussions of several of these concepts, see ***Nonlinear Multiobjective Programming; Sampling Methods; Solving Stochastic Programs; and Stochastic Mixed-Integer Programming Algorithms: Beyond Benders' Decomposition.***

SOLVING LINEAR PROGRAMMING PROBLEMS GRAPHICALLY

Solving a linear programming problem to optimality initially appears daunting. Consider the powdered fruit drink mix problem discussed in an earlier section; how can one determine the number of packets of *Zesty Lemon* and *Super Zesty Lemon* powdered drink mix to produce in order to maximize profit? An infinite number of solutions are feasible (i.e., satisfy all constraints). One could utilize a *greedy approach* and first produce the maximum amount of the product that is most profitable on a per unit basis (*Super Zesty Lemon*), then make as much of the least profitable product (*Zesty Lemon*) as possible with the resources that remain.

Given the amount of sugar available (800 ounces), daily production of *Super Zesty Lemon* cannot exceed 400 single serve packets (recall that each single serve packet of *Super Zesty Lemon* includes 2 ounces of sugar). The available powdered lemon juice (600 ounces) limits daily production of *Super Zesty Lemon* to 300 single serve packets (each single serve packet of *Super Zesty Lemon* includes 2 ounces of powdered lemon juice). Maximum daily production of *Super Zesty Lemon* can therefore not exceed 300 single serve packets, which would generate a profit of 4800¢ (or \$48.00). This production strategy would use all available powdered lemon juice, and 200 ounces of sugar would remain unused. Since production of *Zesty Lemon* requires powdered lemon juice, no packets of this product can be produced with the remaining resources. Perhaps a solution that would make better use of the sugar would produce a superior profit.

Since a single serve packet of *Zesty Lemon* requires only a single ounce of powdered

lemon juice, one can consider producing the maximum quantity of *Zesty Lemon* possible and then producing as much *Super Zesty Lemon* as possible with the remaining resources. Given the amount of sugar available (800 ounces), production of *Zesty Lemon* could not exceed 400 single serve packets (each single serve packet of *Zesty Lemon* includes 2 ounces of sugar). The available powdered lemon juice (600 ounces) limits production of *Zesty Lemon* to 600 single serve packets (each single serve packet of *Zesty Lemon* includes 1 ounce of powdered lemon juice). Maximum daily production of *Zesty Lemon* therefore cannot exceed 400 single serve packets, which would generate a profit of 4000¢ (or \$40.00). This production strategy would use all available sugar, and 200 ounces of powdered lemon juice would remain unused. At this point it is not possible to produce packets of *Super Zesty Lemon* (which require sugar). Obviously, this solution is inferior (by \$8.00) to the greedy solution identified in the previous paragraph.

One may also wish to consider solutions that involve production of some amount of each product; such a solution may make better use of the available resources (sugar and powdered lemon juice) and produce a superior profit. Note that for every packet of *Zesty Lemon* that is removed from the solution identified in the previous paragraph, one sacrifices 10¢ of profit and makes available 2 ounces of sugar and 1 ounce of powdered lemon juice. These resources could be combined with one of the remaining ounces of the powdered lemon juice to produce one packet of *Super Zesty Lemon*, which will generate 16¢ of profit (for a net gain of 6¢ of profit). If this were done 200 times, the number of packets of *Zesty Lemon* produced would decrease by 200 and the corresponding contribution to profit would fall by 2000¢, while the number of packets of *Super Zesty Lemon* produced would simultaneously increase by 200 and the corresponding contribution to profit would be 3200¢. The net result would be an increase of 1200¢ (or \$12.00) of profit over the strategy of producing only packets of *Zesty Lemon*. The new solution is to produce 200 packets of *Zesty Lemon*

and 200 packets of *Super Zesty Lemon* and generate a profit of 5200¢ (or \$52.00). This result suggests that if one can effectively manage the trade-offs in the marginal profits generated by the two products, one can potentially identify superior solutions to the problem (and perhaps even identify an optimal solution to the problem).

So how does one manage these trade-offs in a systematic manner? This task is surprisingly straightforward and simple. In the case of a linear programming problem involving only two decision variables, an optimal solution can be found using basic geometry and algebra in tandem. One can

- plot the areas represented by the constraints (i.e., identify the area that is feasible for each constraint);
- find the feasible region for the problem (the intersection of the areas that are feasible with respect to the constraints);
- set the objective function equal to some arbitrary value and plot the resulting equality; (this is referred to as an *isoprofit line* or *objective contour*);
- move this isoprofit line in a parallel fashion through the feasible region in the direction of improvement with respect to the objective function, stopping when the parallel-shifted isoprofit line is tangent to the feasible region;
- convert the constraints that intersect at this optimal solution to equalities, and then solve these equalities with respect to the decision variables; this will yield the optimal values of the decision variables associated with this optimal solution; and
- substitute the optimal values of the decision variables into the objective function and solve; this will yield the optimal objective function value.

Again consider the powdered fruit drink mix problem from the previous section; because this problem has only two decision variables, it can be solved graphically using the steps outlined above.

- Plot the areas represented by the constraints (i.e., identify the area that is feasible for each constraint).

Let the x -axis represent X_1 (the number of packets of *Zesty Lemon* powdered drink mix produced) and the y -axis represent X_2 (the number of packets of *Super Zesty Lemon* powdered drink mix produced). The regions that satisfy each of the constraints and their intersection (the feasible region) are shown on the graph in Fig. 1:

- Set the objective function equal to some arbitrary value and plot the resulting isoprofit line. Set the objective function equal to 3200¢, that is,

$$10X_1 + 16X_2 = 3200,$$

and plot the resulting isoprofit line (Fig. 2).

- Move this isoprofit line in a parallel fashion through the feasible region in the direction of improvement with respect to the objective function, and stop when the parallel-shifted isoprofit line is tangent with the feasible

region; this is an optimal solution (Fig. 3).

- Convert the constraints that intersect at this optimal solution to equalities, and then solve these equalities with respect to the decision variables; this will yield the optimal values of the decision variables associated with this optimal solution.

After converting the sugar and powdered lemon juice constraints to equalities, solving for X_1 (packets of *Zesty Lemon*) and X_2 (packets of *Super Zesty Lemon*) at this point yields

$$2X_1 + 2X_2 = 800$$

$$\begin{array}{r} -(X_1 + 2X_2 = 600) \\ \hline X_1 = 200, \end{array}$$

and

$$\begin{aligned} X_1 + 2X_2 &= 600 \rightarrow 200 + 2X_2 \\ &= 600 \rightarrow X_2 = 200. \end{aligned}$$

The optimal values of the decision variables X_1 (packets of *Zesty Lemon*) and X_2 (packets of *Super Zesty Lemon*) are 200 and 200, respectively.

Figure 1. Feasible Region for the Powdered Drink Mix Problem.

Figure 2. The Iso-Profit Line Corresponding to a 3200¢ Profit.

Figure 3. Parallel Shifting the Iso-Profit Line in the Direction of Improvement until it is Tangent to the Feasible Region.

- Substitute the optimal values of the decision variables into the objective function and solve; this will yield the optimal objective function value.

Substitution of the optimal values of the decision variables X_1 (packets of *Zesty Lemon*) and X_2 (packets of *Super Zesty Lemon*) yields

$$\begin{aligned}
 10X_1 + 16X_2 &= 10(200) + 16(200) \\
 &= 5200,
 \end{aligned}$$

and so the optimal objective function value is 5200¢ (\$52.00).

SOLVING LINEAR PROGRAMMING PROBLEMS THROUGH ENUMERATION

Each constraint has a perimeter that can be found by setting the left hand side of the constraint equal to the right hand side of the constraint. If feasible, the points where perimeters of constraints (including nonnegativity) intersect are called *extreme points* and are extremely important. By the *Fundamental Theorem of Linear Programming*, an optimal solution to the linear programming problem (if one exists) can be found at an extreme point due to the linearity of the objective function and the convexity of feasible region (see Dantzig [2] for a detailed explanation and Martin [3] for a succinct proof). This discussion now considers linear programs for which an optimal solution exists; discussion of linear programs for which no

optimal solution exists is provided in the section titled “Special Cases” that follows.

In linear programming, the enumeration method refers to the determination of an optimal solution (if one exists) through the evaluation of the solution at each point of intersection of perimeters of constraints. Note that this set of points includes all extreme points and so, by the fundamental theorem of linear programming, will include an optimal solution (if one exists). This means that for the powdered fruit drink mix problem, an optimal solution may be found at one or more of points A, B, C, D, E, and F identified in Fig. 4. Solving for the decision variables X_1 and X_2 at each of these points yields the solutions provided in Table 1.

Of these solutions, points C and F have the largest objective function values (6400 and 6000, respectively); however, neither of these solutions is feasible (point C violates the powdered lemon juice constraint and point F violates the sugar constraint). Of the remaining points (each of which is feasible and so is an extreme point), point D provides the largest objective function value. Thus, through the enumeration method one would again identify the optimal solution as

Figure 4. Points to be considered in solving the powdered drink mix problem by enumeration.

Table 1. Solutions at the Intersections of Perimeters of Constraints

Extreme Point	X_1 (packets of <i>Zesty Lemon</i>)	X_2 (packets of <i>Super Zesty Lemon</i>)	Objective Function
A	0	0	0
B	0	300	4800
C	0	400	6400
D	200	200	5200
E	400	0	4000
F	600	0	6000

point D, where $X_1 = 200, X_2 = 200$, and the objective function is 5200.

A linear program with n decision variables and $m + n$ constraints (which includes n nonnegativity constraints) will require evaluation of as many as $\binom{m+n}{n}$ solutions when using the enumeration method. This implies that the enumeration method requires evaluation of (i) potentially several infeasible solutions and (ii) all extreme points—these are the inherent weaknesses of the enumeration method. Enumeration of a relatively small linear program with 100 decision variables and 150 constraints (including nonnegativity) may require the evaluation of as many as $2.01287\text{E} + 40$ potential solutions. In order for an algorithm to be practical, it must be able to quickly find an optimal solution for linear programs with thousands or even millions of constraints and decision variables, and this can only be accomplished if the algorithm avoids these inherent weaknesses of the enumeration method.

SOLVING LINEAR PROGRAMMING PROBLEMS WITH THE SIMPLEX ALGORITHM

Real applications of linear programming frequently feature far more decision variables and constraints than can be solved for efficiently through graphing or the enumeration method. For such problems, the *simplex algorithm* is often used to find an optimal solution. This algorithm was created by George Dantzig, who is also credited with the first use of the term *linear programming* in reference to problems in logistics programs that he worked on for the Allied Forces during

World War II [4]. The algorithm relies on a corollary of the fundamental theorem of linear programming and successfully addresses the inherent weaknesses of the enumeration method discussed in the proceeding discussion; the simplex algorithm generally (i) will require the evaluation of only a subset of all extreme points and (ii) will not require the evaluation of infeasible solutions.

One can think of the simplex algorithm as a systematic approach to solving a series of simultaneous equations for a set of variables with unknown values in a manner that best satisfies the objective function. For example, again consider the powdered fruit drink mix problem; for the first constraint (sugar), it is obvious that values of the decision variables X_1 and X_2 must be chosen so that the resulting value on the left side of the inequality (ounces of sugar used to produce *Zesty Lemon* and *Super Zesty Lemon*) does not exceed the value on the right side of the inequality (ounces of sugar available). This inequality can be converted into an equality by adding a nonnegative variable (designated S_1) to the left side of this constraint, where S_1 is defined to be equal to the number of ounces of unused sugar, that is,

$$S_1 = 800 - (2X_1 + 2X_2).$$

The resulting equality is

$$2X_1 + 2X_2 + S_1 = 800,$$

and S_1 is referred to as the *slack variable* associated with the first constraint. The second constraint (powdered lemon juice) can be converted to an equality in a similar manner

$$X_1 + 2X_2 + S_2 = 600,$$

where

$$S_2 = 600 - (X_1 + 2X_2).$$

Here, S_2 is referred to as the *slack variable* associated with the second constraint and represents the ounces of unused powdered lemon juice sugar that remain if one produces X_1 packets of *Zesty Lemon* and X_2 packets of *Super Zesty Lemon*. Since neither S_1 nor S_2 contributes to the objective function, these variables both have objective function coefficients of 0. The resulting revised formulation, called the *standard form* of the original formulation, is

$$\begin{aligned} \text{Maximize } & 10X_1 + 16X_2 + 0S_1 + 0S_2 \\ & 2X_1 + 2X_2 + S_1 = 800 \\ & X_1 + 2X_2 + S_2 = 600 \\ & X_1 \geq 0 \\ & X_2 \geq 0 \\ & S_1 \geq 0 \\ & S_2 \geq 0. \end{aligned}$$

The result is a system of $m = 2$ equalities and $n + m = 4$ variables

$$\begin{aligned} 2X_1 + 2X_2 + S_1 &= 800, \\ X_1 + 2X_2 + S_2 &= 600, \end{aligned}$$

for which the nonnegativity constraints provide the conditions under which one can ignore a solution to this set of equations due to infeasibility. Note that a constraint for which the left hand side must be at least as large as the right hand side can be converted to an equality in a similar manner by subtracting a surplus variable (defined as the amount by which the left hand side exceeds the right hand side) from the left hand side of the constraint.

With m equalities one can find unique values for no more than m variables; thus solving a system of equations such as this will generally involve setting n of the decision variables, slack variables, and surplus variables equal to 0 (these are referred to as *nonbasic variables*) and solving for the remaining m variables (these are referred

to as *basic variables*). Thus, at each iteration for the powdered drink mix problem, the simplex algorithm systematically solves for two of the variables in this set of simultaneous equations while setting the remaining two variables equal to zero, and then evaluates the resulting solution with respect to the objective function.

One begins by identifying a feasible solution at an extreme point and evaluating the objective function at that point; this is called the *current solution*. Movement of the current solution toward adjacent extreme points is then considered. Note here that moving from an extreme point that represents the current solution to an adjacent extreme point is equivalent to allowing one of the nonbasic variables (i.e., variables with values of zero in the current solution) to become basic (i.e., potentially take on a positive value). If none of these adjacent extreme points produces a superior objective function value, then the current solution is an optimal solution. On the other hand, if any of these adjacent extreme points produces an objective function value that is superior to the value produced by the current solution, the adjacent extreme point that produces the best marginal increase per unit of the new basic variable becomes the current solution. These steps constitute one *iteration* of the algorithm, and the process continues until no adjacent extreme point produces a value of the objective function that is superior to the current solution.

If one initializes the simplex algorithm on the powdered drink mix problem by arbitrarily selecting X_1 and X_2 to be nonbasic variables (i.e., setting $X_1 = 0$ and $X_2 = 0$), the slack variables become basic variables and take on the values $S_1 = 800$ and $S_2 = 600$; this yields an objective function value of 0. This is reasonable—if one produces no packets of *Zesty Lemon* (X_1) or *Super Zesty Lemon* (X_2), 800 ounces of sugar (S_1) and 600 ounces of powdered lemon juice (S_2) will remain and no profit will be earned. This solution occurs at the origin, which is extreme point A in Fig. 4, and is the initial current solution.

Now consider swapping the roles of one basic variable and one nonbasic variable in this solution. Which of the basic variables (S_1

or S_2) should be set to 0 (i.e., made nonbasic), and which of the nonbasic variables (X_1 or X_2) should be allowed to potentially take a nonzero value (i.e., become basic)? In other words, does increasing the value of X_1 or X_2 by one unit increase the objective function value, and if so, for which of these variables will a one unit increase result in the greatest marginal improvement in the objective function value?

A one unit increase in X_1 will contribute 10¢ directly to the objective function while decreasing the slack (leftover) ounces of sugar by 2 ounces and the slack (leftover) ounces of powdered lemon juice by 1 ounce. Since neither the slack (leftover) ounces of sugar nor the slack (leftover) ounces of powdered lemon juice contributes to the objective function, there is no cost associated with using either resource, and so the marginal contribution to the objective function that is made by increasing X_1 by one unit at this iteration is 10¢.

Similarly, a one unit increase in X_2 will contribute 16¢ directly to the objective function while decreasing the slack (leftover) ounces of sugar by 2 ounces and the slack (leftover) ounces of powdered lemon juice by 2 ounces. Again, since neither the slack (leftover) ounces of sugar nor the slack (leftover) ounces of powdered lemon juice contributes to the objective function, there is no cost associated with using either resource, and so the marginal contribution to the objective function that is made by increasing X_2 by one unit at this iteration is 16¢.

Since the marginal increase in the objective function associated with a one unit increase in X_2 is 16¢ and the marginal increase in the objective function associated with a one unit increase in X_1 is 10¢ at this iteration, X_2 is allowed to potentially take some positive value (i.e., become basic). Note that these marginal values are often referred to as *reduced costs*. The algorithm continues to increase the value of X_2 until some variable that is basic in the current solution (S_1 or S_2) becomes nonbasic, which at this iteration means that the supply of either sugar or powdered lemon juice is exhausted. This occurs at $X_2 = 300$, which results in $S_1 = 200$

and $S_2 = 0$ (the supply of powdered lemon juice that remained in the previous iteration is exhausted) and yields an objective function value of 4800. If one produces 0 packets of *Zesty Lemon* (X_1) and 300 packets of *Super Zesty Lemon* (X_2), 200 ounces of sugar (S_1), and 0 ounces of powdered lemon juice (S_2) will remain, and 4800¢ profit will be earned; this solution occurs at extreme point B in Fig. 4 (which is adjacent to the extreme point A).

Note that if one had allowed X_1 to become basic (potentially take some positive value) and continued to set $X_2 = 0$ in the first iteration, the value of X_1 would have become 400 and as a result $S_1 = 0$ and $S_2 = 200$, which would have yielded an objective function value of 4000. If one produces 400 packets of *Zesty Lemon* (X_1) and 0 packets of *Super Zesty Lemon* (X_2), 0 ounces of sugar (S_1) and 200 ounces of powdered lemon juice (S_2) will remain and 4000¢ profit will be earned; this solution occurs at extreme point D in Fig. 4 (which is the other extreme point that is adjacent to the extreme point A).

All extreme points that are adjacent to the current solution have now been systematically examined, and both result in objective function values that are superior to the objective function value produced by the current solution. The algorithm therefore selects extreme point B (the extreme point at which X_2 , the nonbasic variable that makes the greatest per unit improvement to the objective function of all nonbasic variables at this iteration, becomes basic) as the new current solution. $X_1 = 0, X_2 = 300, S_1 = 200, S_2 = 0$, and profit = 4800. Evaluation of all extreme points that are adjacent to a current solution constitutes one iteration of the simplex algorithm, and the algorithm will continue to iterate until no improvement to the objective function value that is associated with the current solution can be found; at that point an optimal solution has been identified.

Now, again consider allowing one of the nonbasic variables (i.e., a variable with a value of 0 in this new current solution) to become basic (take a positive value). A one-unit increase in X_1 will directly contribute

10¢ to the objective function. However, note that production of one unit of X_1 requires 2 ounces of sugar and 1 ounce of powdered lemon juice, and the supply of powdered lemon juice is exhausted by the current solution. The only way to increase the number of units of X_1 by one is to use some powdered lemon juice that is currently devoted to production of X_2 . Since it takes 2 ounces of powdered lemon juice to produce one unit of X_2 and only 1 ounce of powdered lemon juice to produce one unit of X_1 , one must sacrifice $\frac{1}{2}$ unit of X_2 for every unit of X_1 added at this iteration. Since one unit of X_2 makes a direct contribution of 16¢ to the objective function, the loss of $\frac{1}{2}$ unit of X_2 decreases the objective function by 8¢. Because the slack (leftover) sugar at this iteration is positive, it can be used in the production of X_1 at no cost. Thus, the marginal increase in the objective function at this iteration that corresponds to a one unit increase in X_1 is $10¢ - 8¢ = 2¢$. The algorithm will continue to add units of X_1 until one of the basic variables for this iteration (X_2 or S_2) becomes nonbasic (i.e., becomes 0). This occurs at $X_1 = 200$ and $X_2 = 200$, with $S_1 = 0$ (the slack sugar that remained in the previous iteration is now exhausted) and $S_2 = 0$, which yields an objective function value of 5200¢. This becomes the current solution, and the second iteration is complete.

At this point, one could consider allowing one of the slack variables (each of which equals 0 in this new current solution) to take a positive value. However, a one unit increase in either slack variable S_1 or S_2 will not improve the objective function, so the algorithm stops at this iteration. The optimal solution to this problem is $X_1 = 200, X_2 = 200, S_1 = 0$, and $S_2 = 0$, which yields an objective function value of 5200¢.

In reviewing these iterations, it is apparent that in each iteration the simplex algorithm started at an extreme point (the current solution at that point), considered all adjacent extreme points, and moved to the extreme feasible point that yielded the greatest marginal contribution to the objective function per unit increase of the associated new basic variable.

Because the simplex algorithm considers only a subset of extreme points and completely ignores infeasible solutions, it is referred to as an *intelligent enumeration algorithm*. It is for these reasons that the simplex algorithm is remarkably efficient and capable of quickly solving very large problems to optimality in a relatively short period of time [5,6]. For a more detailed discussion, see **The Simplex Method and Its Complexity** and **Simplex-Based LP Solvers**.

SPECIAL CASES

Note that it is possible for multiple extreme points to be optimal; under these circumstances, these multiple extreme points and all points that lie on the perimeter of the constraint that connects them have the same value of the objective function and are referred to as the *alternate optimal solutions* (or *alternate optima*). This phenomenon occurs when the objective function and the perimeter of a constraint that combines with other constraints to form an optimal extreme point are parallel (for example, if the objective function in the powdered fruit drink problem was Maximize $4X_1 + 8X_2$ as shown in Fig. 5).

For this problem, the objective function and the perimeter of the powdered lemon juice constraint have the same slope, and the powdered lemon juice constraint is one of the constraints that intersect to form an optimal extreme point. Thus, extreme points B and D and all points that lie on the line segment that connects these points are alternate optima.

It is also possible for a linear programming problem to have no optimal solution. This can happen in two distinct ways. Consider the following formulation of a linear programming problem with two decision variables:

$$\begin{aligned} &\text{Maximize } 10X_1 + 16X_2 \\ &\text{subject to } 2X_1 + 2X_2 \geq 800 \\ &\quad X_1 + 2X_2 \geq 600 \\ &\quad X_1 \geq 0 \\ &\quad X_2 \geq 0. \end{aligned}$$

If one graphs the feasible region for this problem and then plots and parallel shifts an

Figure 5. An example of a linear program with alternate optimal solutions.

Figure 6. An example of an unbounded linear program.

isoprofit line in its direction of improvement, one never reaches the perimeter of the feasible region. The feasible region for problems such as this is said to be *unbounded* (Fig. 6).

A linear programming problem also has no optimal solution if there is no feasible region;

this happens when there is no intersection of the areas that are feasible for the individual constraints and is called *infeasibility*. Consider the following formulation of a linear programming problem with two decision variables:

Figure 7. An example of an infeasible linear program.

$$\begin{aligned}
 &\text{Maximize } 10X_1 + 16X_2 \\
 &\text{subject to } 2X_1 + 2X_2 \geq 800 \\
 &\quad X_1 + X_2 \leq 200 \\
 &\quad X_1 \geq 0 \\
 &\quad X_2 \geq 0.
 \end{aligned}$$

A graph of the feasible spaces that correspond to the first two constraints for this problem is provided in Fig. 7. The feasible regions for these two constraints obviously have no intersection (i.e., no solution lies in an area that satisfies both constraints), and so there is no feasible region from which to select a potential solution.

OTHER CONSIDERATIONS

Note that several methods have been developed for assessing the changes in the solution that result from changes in the values of parameters. These methods are collectively referred to as *sensitivity analysis*, *postoptimality analysis*, or more colloquially as *what-if analysis* (see ***Sensitivity Analysis in Linear Programming***).

It is also important to note that this entire discussion pertains to problems for which the objective is to minimize some function of the decision variables. In fact, multiplication of a maximization objective function by -1 creates an equivalent minimization objective function (the converse is also true).

Duality

Associated with every linear programming problem is a unique corresponding formulation that is referred to as the problem's *dual* formulation. In this context, the original problem is referred to as the *primal* formulation.

Conventionally, the primal constraints are indexed by $i = 1, \dots, m$ and the primal decision variables by $j = 1, \dots, n$. Using this indexing scheme, we can denote the objective function coefficient for the j th primal decision variable x_j as c_j , the coefficient associated with the j th primal decision variable in the i th primal constraint as a_{ij} , and the right hand of the i th primal constraint as b_i . If the objective of the primal formulation is maximization of the objective function, all primal decision variables are on the left hand sides and all constants are on the right hand

sides for each constraint, and each primal constraint is expressed such that the left hand side is less than or equal to the right hand side, the generic formulation using this notation is

$$\begin{aligned} &\text{Maximize} && \sum_{j=1}^n c_j x_j \\ &\text{subject to} && \sum_{j=1}^n a_{ij} x_j \leq b_i \quad i = 1, 2, \dots, m \\ &&& x_j \geq 0 \quad j = 1, 2, \dots, n. \end{aligned}$$

This is referred to as the *standard form* of the primal problem. Note that any linear program can be put into this form through basic algebra.

If the primal formulation is in the standard form, then the goal of the associated dual formulation is minimization of its objective function. The associated dual formulation will have a decision variable corresponding to each primal constraint and a constraint corresponding to each primal decision variable. Thus the dual constraints are indexed by $j = 1, \dots, n$ and the dual decision variables by $i = 1, \dots, m$. The dual decision variables may be denoted by y_i .

The objective function coefficient for the i th dual decision variable y_i is the right hand of the i th primal constraint b_i , the coefficient associated with the i th dual decision variable in the j th dual constraint is a_{ji} , and the right hand of the j th dual constraint is the objective coefficient of the j th primal variable c_j . Finally, if primal problem is in standard form (i.e., the left hand side of each primal constraint is restricted to be less than or equal to its corresponding right hand side), then the left hand side of each constraint in the corresponding dual problem is restricted to be greater than or equal to its corresponding right hand side. Given these relationships and the primal formulation in standard form, the corresponding generic dual formulation is

$$\text{Minimize} \quad \sum_{i=1}^m b_i y_i$$

$$\begin{aligned} &\text{subject to} && \sum_{i=1}^m a_{ji} y_i \geq c_j \quad j = 1, 2, \dots, n \\ &&& y_i \geq 0 \quad i = 1, 2, \dots, m. \end{aligned}$$

For example, the dual formulation associated with the powdered fruit drink mix problem is

$$\begin{aligned} &\text{Minimize} && 800Y_1 + 600Y_2 \\ &\text{subject to} && 2Y_1 + Y_2 \geq 10 \\ &&& 2Y_1 + 2Y_2 \geq 16 \\ &&& Y_1 \geq 0 \\ &&& Y_2 \geq 0, \end{aligned}$$

with an optimal solution of $Y_1 = 2$ and $Y_2 = 6$, and an associated objective function value of 4800. Note that the optimal objective function values associated with the primal and dual formulations for this problem are equal; this will always be so, and this result is referred to as the *strong duality theorem* (which is discussed shortly).

While the dual formulation can yield additional insightful information and can sometimes be solved to optimality in less time than the corresponding primal formulation, the greatest value of the dual formulation lies in three results on the relationship between a primal formulation and its corresponding dual formulation.

The first of these results is commonly referred to as the *weak duality theorem*. This theorem states that for a primal formulation in standard form, the objective function value of the associated dual problem at any of its feasible solutions will be greater than or equal to the objective function value of the primal problem at any of its feasible solutions. Thus, if a primal problem is in standard form, given any feasible primal solution $x_1, x_2, \dots, x_n$ and any feasible solution $y_1, y_2, \dots, y_m$ for the associated dual,

$$\sum_{j=1}^n c_j x_j \leq \sum_{i=1}^m b_i y_i.$$

This relationship allows for the identification of an upper bound for the primal problem objective value through the identification of

a feasible solution of the corresponding dual problem. Similarly, if the goal of the primal formulation is minimization of its objective function, the objective function value of any feasible solution of the associated dual problem will be less than or equal to the objective function value of any feasible solution of the primal problem (and so constitutes a lower bound for the primal problem objective value).

The second of these three results is referred to as the *complementary slackness theorem*. This theorem states that for any feasible primal solution $x_1, x_2, \dots, x_n$ and any feasible solution $y_1, y_2, \dots, y_m$ for the associated dual

$$\left(b_i - \sum_{j=1}^n a_{ij}x_j\right)y_i = 0 \quad i = 1, 2, \dots, m,$$

which is referred to as *primal complementary slackness*, or conversely

$$\left(c_j - \sum_{i=1}^m a_{ji}y_i\right)x_j = 0 \quad j = 1, 2, \dots, n,$$

which is referred to as *dual complementary slackness*. Either of these sets of conditions is also commonly referred to as the *optimality conditions* as they constitute necessary and sufficient conditions for optimality of the primal or dual problem.

Complementary slackness, in combination with requirements for feasibility of the primal and dual solutions, comprise what are known as the *Karush–Kuhn–Tucker* (or *KKT*) *optimality conditions* [7].

The third of these results is commonly referred to as the *strong duality theorem*. This theorem, which is often cited as a lemma of complementary slackness, states that if the primal problem has an optimal solution $x_1^*, x_2^*, \dots, x_n^*$, then the associated dual problem also has an optimal solution $y_1^*, y_2^*, \dots, y_m^*$ such that

$$\sum_{j=1}^n c_j x_j^* = \sum_{i=1}^m b_i y_i^*,$$

that is, if the primal formulation has an optimal solution, the associated dual problem

also has an optimal solution with an objective function value equal to the optimal primal objective value. This relationship allows for the solution of a primal problem through the formulation and solution of the corresponding dual problem.

An important corollary of the strong duality theorem states that if a primal linear program is unbounded, then the associated dual linear program is infeasible (and the converse is also true).

For proof of these theorems and the corollary associated with the strong duality theorem see [3].

Interior Point Methods

While the solution algorithms discussed in this article search the perimeter of the feasible region (and sometimes beyond) for an optimal solution, other solution algorithms search for an optimal solution by moving directly through the interior of the feasible region. These algorithms are referred to as *interior point methods* [8,9]. While early work in this area by Khachian [10] on what is referred to as the *ellipsoid method* ultimately showed initial promise, it was Karmarkar's efforts [11] that first demonstrated the true potential of interior point algorithms for solving large linear programs efficiently. Modern solution algorithms that are based on interior point methods often have better worst-case running times than the simplex algorithm, and are commonly used in practice to solve large linear programs [12,13]. See **Interior-Point Linear Programming Solvers** for a more detailed discussion of this concept.

Finally, it is important to reiterate that (i) large linear programming problems can generally be solved to optimality rapidly and (ii) many problems faced by small businesses and scientists across disciplines can be solved using linear programming.

AN INTRODUCTION TO PLATELET INVENTORY AND ORDERING PROBLEMS

JOHN T. BLAKE
Department of Industrial Engineering,
Dalhousie University,
Halifax, Nova Scotia, Canada

BACKGROUND

Platelets are blood cells that initiate the hemostatic plug that causes blood clot formation. Patients receiving intense chemotherapy or suffering massive bleeding complications require platelet transfusions for the prevention of a potentially fatal hemorrhage. A stable, readily available inventory of platelets is required for the safe and effective delivery of health care [1].

Platelets are typically produced from whole blood through a process that separates blood into three main products: red cells, plasma, and platelets. Platelets can also be collected directly through apheresis, a donation process that removes platelets and some plasma from a donor's blood, and returns the remaining red cells and plasma back to the donor's system.

Since platelets must be kept warm to remain viable, they are subject to bacterial contamination and thus have a shelf life of 5–7 days. The exact shelf life of platelets depends on the method used to collect platelets from donors and the use of systems to detect bacterial contamination. The short shelf life poses a number of inventory management problems. Since transmissible disease testing, component processing, nucleic acid testing, and blood bank testing require 12–48 h to complete, platelets may be available for transfusion for as little as 78 h before they must be discarded. By comparison, red blood cells have a shelf life of 42 days at present; though there is some

indication that the older red cells may be less effective than the newer cells [2].

PLATELET INVENTORY AND ORDERING PROBLEM

Managing platelet inventory is a difficult problem because of the necessity of minimizing both stock-outs and outdates. Since they are vital for medical care, an adequate supply of platelets must be available on demand. Since supply and demand are stochastic, hospitals and blood product suppliers must maintain stock to minimize stock-outs. However, because platelets are perishable, excess inventory leads to outdates. Both stock-outs and outdates are considered to be expensive. Stock-outs are expensive in an absolute sense because patients may suffer ill-health (or worse) without a timely transfusion of platelets. In a practical sense, a shortage of platelets requires a hospital or blood supplier to expedite platelets from another source (another distribution center or hospital), often with a large resultant cost penalty. Outdates are also considered to be expensive. There is, of course, the tangible cost of the materials and labor required by the blood supplier to collect, produce, test, and distribute the unit, as well as the cost to the hospital of receiving and storing a unit that ultimately was never needed. There is also an intangible cost to the donor of having lost personal time and suffering discomfort to provide a unit that ends up being incinerated. Blood agencies are sensitive to the intangible costs to donors, since they feel that individuals may be less inclined to donate if they think that their gift will just be scrapped. Because donor participation rates in western countries are typically less than 5% of the eligible adult population [3], large outdatedness rates are believed to be a threat to the underlying stability of the blood supply chain and must be avoided.

DEFINITION OF PRODUCER'S AND CONSUMER'S PROBLEM

There are two subproblems in platelet inventory and ordering: the producer's problem and the consumer's problem.

Producer's Problem

The producer's problem follows a classical inventory management structure. At the beginning of each decision epoch (typically a day), the inventory state, comprising the total number of units available and their age distribution, is observed. The decision maker places an order for platelets to be collected during the day, before demand is observed. Collections are usually assumed to be deterministic. A nonzero cost for placing an order is assumed ($c_o = f_o + v_o o$). Orders are assumed to take a minimum of one period to be filled. Thus, orders placed today are not available for distribution until tomorrow.

Demand is observed over the course of the day. Demand is assumed to be stochastic and unknown by the producer prior to its realization, but to follow a known distribution. The producer fills the demand from the available stock, starting with the oldest stock on hand (i.e., a first-in-first-out or FIFO policy). If orders cannot be filled from the available stock, a shortage is registered and the unmet demand is assumed to have been lost. A penalty is assumed for any shortage. It is generally assumed that any instance of a shortage is to be avoided and thus, a step-type penalty cost with a large fixed component and a small per unit cost is often assumed ($c_S = f_S + v_S S$).

At the end of each day, all stock remaining in the inventory is "aged" by 1 day. For example, the stock that will expire in 2 days becomes the stock that will be outdated in 1 day. Any remaining stock with 1 day to outdate becomes stock with 0 days to outdate and is thus "outdated" and removed from the inventory. A nonzero outdate cost is assumed, generally with both a fixed and variable component ($c_W = f_W + v_W W$). It is generally assumed that $c_S \gg c_W$.

Finally, the stock that was ordered yesterday becomes available for use and enters

inventory as m day to outdatedness stock. The cycle then repeats.

It should be noted that stock on hand is typically represented as a vector $\mathbf{x} = (x_1, x_2, \dots, x_m)$, where x_i is the inventory with i days to outdate. Thus, the stock vector is typically "backwards" with x_1 representing the oldest stock on hand (i.e., the stock with 1 day to outdate) and x_m representing the newest stock (i.e., the stock with m days to outdate).

Consumer's Problem

The consumer's problem is similar to the producer's problem with two important differences. As in the producer's problem, the inventory state, comprising the number of units available and their age distribution, is observed at the beginning of the decision epoch. A decision is then made about the number of units to order (if any). However, unlike the producer's problem, a consumer's order may be assumed to arrive before demand is observed. This assumption is reasonable for most medium to large hospitals in which it might be expected that an order could be received within a few hours from a nearby distribution center. In instances where deliveries cannot be made within a few hours, such as rural or isolated facilities, orders must be made 1 or more days in advance and the problem more closely resembles that of the producer's problem.

Unlike the producer's problem, the units arriving to the consumer may or may not be of a consistent age. For instance, the consumer may receive some units with 5 days to outdate, some with 4 days to outdate, and so on. Since distribution and testing often take 1 or more days to complete, it is rare for consumers to receive "new" products; more commonly, consumers receive products that have lost 1 or more days of shelf life prior to receipt. Furthermore, because of the variations in collection and production schedules at the producer, (day-to-day fluctuations in collections as well as a systematic fluctuation occurring because demand is experienced 7 days a week while platelet collection and testing may occur only Monday to Friday), the age of arriving units varies from day to day. For instance,

platelets collected on Fridays, are typically not available for distribution until Monday and thus, consumers receive platelets that have lost at least 2 days of shelf life.

LITERATURE REVIEW

There is an extensive literature on perishable inventory as related to blood supply. However, much of the literature deals with red blood cells that have a much longer shelf life than platelets.

Veinott [4] describes a periodic review policy under the assumption of stationary demand. Results show that optimal ordering policies for perishable inventory correspond closely to the nonperishable case. Optimal order quantities are set as

$$\min(Q^*, \lambda m) \quad (1)$$

where Q^* is the economic order quantity (EOQ), λ the demand rate, and m the lifetime. Under this set of assumptions, no units expire.

Pierskalla and Roach [5] use a dynamic programming (DP) formulation to show that FIFO policies are optimal in perishable inventory problems.

Fries [6] describes a DP approach to perishable inventory policies under the assumption of no backordering. Ordering policies in this case depend on the stock on hand, its age distribution, and the length of the planning horizon. Fries considers three specific cases. In instances where the shelf life (m) of the product is one period, the problem reduces to that of the well-known newspaper vendor problem. When the shelf life is two or more periods and the planning horizon (n) is 1 day, the optimal policy is an (s, S) type policy where a quantity of product is ordered to bring the inventory on hand up to a critical value x^* . When the planning horizon is $1 < n < m$ the ordering policy is an (s, S) policy, where an order is placed to bring the total usable inventory on hand in the next period up to y^* , where y^* depends on the age of the stock on hand. When the planning horizon is greater than the life span of the product, the optimal ordering policy is based on the

expected number of units to be consumed in the next period and the age distribution of the remaining stock.

Nahmias [7] adopts a similar approach to Fries, but notes the extreme difficulty of computing optimal policies when m is greater than 2 days. In place of exact solutions, Nahmias argues for the use of heuristic solutions [8,9] and [10] provides an excellent summary of the relevant perishable inventory literature.

Cohen *et al.* [11], acknowledging the problem of *a priori* shortage rates, suggest a simple decision rule that obviates the need for managers to set explicit rates in the case of red blood cell supply. Using regression techniques in combination with simulation methods, they develop a target inventory level S^* that depends on daily demand, average transfusion-to-cross match ratio and cross match release period. Brodheim *et al.* [12] adopt a similar approach, but suggest an equation for setting target inventory that depends on the mean daily demand in conjunction with an explicit management decision regarding acceptable shortage rates. Brodheim and Prastacos [13] describe a model for setting hospital inventory policies under the assumption of a fixed delivery schedule from the regional blood bank.

Kendall and Lee [14] employ a goal-programming approach to develop policies for red cell rotation in blood provision networks. Their model is novel in that it does not take a cost minimization approach, but rather focuses on obtaining a set of objectives that includes minimizing shortages and avoiding outdatedness, both on the local and regional levels. Kendall and Lee note that blood networks vary greatly in their composition and usage patterns and thus suggest that what constitutes a good inventory policy depends on local demand patterns, transportation links, and donor availability and participation rates. Results from tests on two blood networks suggest that outdates are minimized when stock is able to freely rotate between hospitals. Stock age and outdate rates were shown to improve with greater rotation without any increase in shortages. However, Kendall and Lee do not explicitly consider transportation costs

and thus note that hospital mix, geography, and population affect the generalizability of their results.

Freidman *et al.* [15] describe the use of simulation to set inventory levels for red blood cells under the assumption of a 35-day shelf life. Describing blood management policies from a clinician's standpoint, they argue against the setting of *a priori* shortage rates. Instead, they suggest an empirical approach to inventory policy in which safety stocks are gradually reduced.

Hesse *et al.* [16] describe an application of inventory management techniques to platelets, in a system in which a centralized blood bank supplies 35 client hospitals. Hesse *et al.* adopt a periodic review model and develop (s, S, t) policies for each of the client institutions, using a simulation model as a test platform. Noting the complexity of a DP approach, the authors aggregate institutions into risk pools and develop, via an enumerative process, an (s, S, t) policy for each pool.

Sirelson and Brodheim [17] use simulation to test platelet ordering policies for a blood bank, based on the average demand and a fixed base stock level. They show that a base stock level based on a mean demand plus a multiple of standard deviation, can be used to reduce current outdatedness and shortage rates. They also show that, on a regional level, low shortage and outdatedness rates can be readily obtained; within individual hospitals, low outdatedness and shortage rates are more difficult to achieve. Katz *et al.* [18] report similar results.

Blake *et al.* [1] present a DP formulation for solving an instance of the platelet inventory problem for an environment in which there is a single producer of platelets and a single consumer. They implement a DP model for both the producer and the consumer, to identify optimal local ordering policies. These policies are then tested via a simulation model to identify good practical policies that minimize the overall wastage and outdatedness rates. Blake *et al.* note the potential for developing a DP approach for developing optimal joint producer/consumer policies, but found that the so-called *curse of dimensionality* limited the scale of their model, despite efforts to minimize the state space by

aggregating units and demand into standard adult doses.

Katsaliaki and Brailsford [19] describe the use of a large-scale simulation model to evaluate the function of a blood supply chain in southern England. Their model includes multiple products, including platelets. A number of operational policies are tested via simulation. For the system under study (in the simplest case a single producer and a single consumer), it is shown that the amount of inventory stored can be reduced if improved ordering and cross-matching policies are implemented. The single consumer–single supplier model is extended to cover a longer run period and a larger number of consumers through a distributed simulation environment [20].

van Dijk *et al.* [21] suggest a multistep procedure for identifying a heuristic solution to the platelet ordering problem. They formulate the solution to the platelet ordering problem as a DP problem using standard conventions. However, to make the problem tractable, they scale the problem by a factor of 4, since platelet units produced from red cells are typically given to adults in doses of four. van Dijk *et al.* then solve exactly the downsized problem, using a scaled demand function. The solution to the problem is recorded for all instances of day, time in the planning horizon, and amount and age distribution of stock. A simulation model then records 1M weeks of ordering behavior under the assumption of the downsized problem. For each day, the amount of stock on hand and the order size suggested by the DP model are recorded. The resulting order sizes tend to follow a classical “order-up-to” policy seen in the nonperishable inventory problem. Based on this observation, van Dijk *et al.* suggest that solutions to the platelet ordering problem could ignore the age distribution of stock and condition orders only on the total stock available. The order-up-to rule selected for each day is the solution most frequently seen in the simulated history. The solution is then rescaled back to the original problem size and the full-size problem is again simulated to verify that the solution remains feasible for the actual problem. Blake [22], however, argues that age cannot always be ignored.

Erhun *et al.* [23] take a systemic view of the platelet supply chain to recommend a series of practical policy improvements for a university-based blood bank. They note the importance of agility to respond to sudden changes in demand level and suggest a collection and testing regime that extends over 7 days of the week and that is explicitly tied to expected demand. They also suggest shortening the platelet rotation horizon, such that small hospitals hold platelets for only a single day before rotating them to larger demand institutions, and improving issuing policies to ensure strict adherence to FIFO policies.

DISCUSSION

For the deterministic inventory problem, it is simple to show, using the EOQ model, how a fixed order point and quantity can be determined if lead time is constant and known. If lead time or demand varies, safety stock is necessary to ensure that enough stock is on hand to guarantee a given level of service that can be realized between order placement and order receipt. In the case where demand varies, it can be shown that a “two-bin” inventory system is optimal. A two-bin system assumes that inventory is reviewed, either continuously or at fixed intervals. If the inventory is below a certain level (called a *trigger level*), then an order is placed. The order size is not fixed, but depends on the actual amount of stock on hand. The policy suggests an “order-up-to rule” that states that, if the inventory level (i) is less than the trigger level (s) an order of size o is placed that will bring the total amount of inventory on hand up to a target level (S) where $o = S - i$. The methods for finding good two-bin policies, while not always simple, are well known for nonperishable products.

Perishable inventory models are much more difficult to solve. While it is known that an exact solution can be found for perishable inventory problems via DP, it is difficult to actually solve a DP model for problems of realistic size. DP is essentially a search across the solution space for a particular problem. All combinatorial problems (of which the platelet inventory ordering problem is an

example), can be solved by naïve enumeration. That is, if we simply check all of the possible combinations of decisions for every possible combination of inventory state, we will eventually find the solution to any problem. The difficulty, in practice, is that the solution space for a realistic size problem may be so large that even the fastest computers, working for hundreds or thousands of years, cannot generate all the possible combinations. Thus, while it is easy to define the platelet ordering problem in a DP format, actually solving such a model is usually impractical.

In the absence of exact solution methods, most research in the area of platelet ordering problem has focused on the solution of either approximate models or the development of heuristic techniques to find good, if not optimal, solutions to the problem quickly. Some researchers have attempted to solve the platelet ordering problem for restricted problem sizes (see Refs 1 and 21). However, even if the size of the problem is restricted and demand is aggregated from units to doses, exact solutions to the platelet ordering problem remain very difficult to obtain. Other researchers have attempted to set platelet inventory policy through a heuristic search of possible trigger points and order-up-to levels. While such models can be used to develop policies that are good, their solution cannot be proven to be optimal.

In addition to being hard to obtain, DP solutions are difficult to characterize and thus, to implement. Solution values depend on the exact number of units on hand, their age distribution, the day of the week, and the particular day in a planning horizon. This makes it difficult to implement a DP solution in practice, since the number of combinations of day, date, inventory status, and expected demand may be in the range of hundreds of millions.

Given that the exact solutions to the platelet problem are hard to calculate and difficult to implement, most research in the area relies on some form of problem simplification or a heuristic approach to produce a usable solution. Heuristics may involve simple rules of thumb, for example ordering up to the expected demand over the expected life span of the platelets, or they

may involve more complicated procedures, such as the one outlined in Ref. 21. There is a trade-off between the quality of a solution obtained and the time required to obtain that solution. More effort implies a better result, but the law of diminishing returns applies to combinatorial problems and, hence, doubling the computational time does not necessarily improve the quality of the solution by a factor of 2.

CONCLUSION

The safe and effective delivery of health care requires that a sufficient supply of platelets be available when and where required. However, because platelets have a very limited shelf life and are expensive to collect and produce, outdates are an important practical concern for hospitals and blood system operators. The platelet inventory problem revolves around identifying policies for ordering and holding platelets such that unit availability is maximized, while ensuring that outdates are minimized. Cost minimization is also a concern, but it is unclear as to how the intangible effects of shortages and outdatedness can be priced relative to one another and also against concrete operational costs.

The platelet inventory and ordering problem can be formulated as a DP problem. Exact solutions can be obtained for small problems. However, the computational complexity associated with DP makes this method intractable for realistically sized problems. Hence, heuristics are generally employed to solve practical problems.

While there is extensive literature on perishable inventory, with much focus on red blood cells, the OR literature on platelet inventory and ordering is surprisingly sparse. Despite the fact that platelet ordering is a very common practical problem with significant impact on human health, it is not well represented in the literature. The platelet inventory and ordering problem therefore, remains a rich area for theoretical development and an avenue for application of operational research with significant impact.

AN INTRODUCTION TO PROBABILISTIC RISK ANALYSIS FOR ENGINEERED SYSTEMS

ELISABETH PATÉ-CORNELL
Department of Management
Science and Engineering,
Stanford University, Stanford,
California

FAILURE RISK ASSESSMENT

The risk of failure of a system includes both, the probabilities and the consequences of the different failure scenarios.¹ It can be described by the probability distribution of the damage per time unit or operation.² For a complex engineered system, one may not have a sufficient statistical database to assess failure probability at the system level using classical frequentist definitions [1]. That may be true because there is not enough experience with the system, because it is not in a stable state, or because failures are too rare to have been observed systematically in the past. In that case, one has to rely on systems analysis and on the Bayesian definition of probability as a rational degree of belief about the chances of occurrence of an event in a specified reference frame [2–4].

Probabilistic risk analysis³ (PRA) has been developed in engineering, in particular

in the nuclear power industry [5] to permit computing the risk in cases where there is insufficient statistical information at the system level, but where some information is available at the level of subsystems or components [6–12]. Events and random variables in the possible scenarios are combined systematically, accounting for dependencies and rare occurrences which are often difficult for the human mind to grasp without analytical support.

A Brief History of PRA

PRA has a rich history. In the nuclear power industry, as mentioned above, it was particularly helpful in providing safety information in the early years of the civilian nuclear power program, when there was limited experience at the system level, but considerable amounts of additional information at the subsystem level, for example from the US nuclear Navy. PRA has been used since then in many other settings, such as chemical plants [13] and space systems [14]. In electrical engineering, the reliability of a circuit can be assessed as a function of the reliability of its components using fault trees to provide a logical (Boolean⁴) relationship between the failure of the whole system and that of its components, in parallel or in series. For instance, Haasl [15] describes the early use of fault trees in the analysis of aviation safety. In civil engineering, one problem is to compute the probability of failure of a structure, given its capacity and the loads to which it may be subjected [16]. When both are uncertain, they can be described by probability distributions. The probability of failure is then computed as the probability

¹In some cases, the problem is to compute only the failure probability per time unit or operation for instance, because the consequences are well known.

²Note that the expected value of the losses is generally not a sufficient description of the risks, especially in cases where rare failures can cause large damage.

³Probabilistic risk analysis (PRA) is also called probabilistic risk assessment, or quantitative risk analysis (QRA) or probabilistic safety assessment or analysis (PSA).

⁴Boolean algebra provides logical relations (e.g., AND and OR functions) among variables that can take values of 1 or 0—true or false—for example, to represent the state—failure or no failure—of an element.

that the loads (for example, the seismic loads) exceed the capacity in a specified time frame.

In mechanical engineering, aeronautics, and astronautics, the same methods have been applied to new and/or complex systems, ranging from automobiles involving new components to space systems.⁵ A probabilistic analysis of the risk of a potential failure of the heat shield of the US space shuttle [17,18] showed that 15% of the tiles that protect the orbiter at reentry represented about 80% of the risk.⁶ More recently, the same probabilistic approach has been used for medical devices, which may need to be tested in patients before they are approved by the Food and Drug Administration [19]. In new systems, with which there is little experience *in situ* such as a new type of satellite or medical device, the failure probability can be computed by a PRA-type of model, based on an analysis of the functions to be performed and on marginal and conditional probabilities of component failures.

PRA allows using all available information to represent uncertainties about a system's performance. The data may include direct observations, surrogate data (same elements in another setting), engineering models, test results, and expert opinions. PRA relies on an analysis of the functions to be performed by the whole system and on the probabilities of failure of its basic components and subsystems. As described by Garrick and Kaplan, the analysis is guided by the questions: What can go wrong? With what probability? And with what consequences? [6]. Similarly, the risk management problem can be described as finding and fixing a system's weaknesses [21] by asking the questions: How does it work? How can it fail? And what can be done about it, given that we are not infinitely rich and that days have only 24 h? The risk assessment results then become inputs into

a problem of risk management and optimization of resource allocation.

As described further, the PRA method relies in part on event trees and fault trees, or similarly, on Bayesian networks (or influence diagrams). It includes the effects of external events that may affect the performance of the components, possibly several at the same time, thus creating dependencies among basic failures. It also includes a consequence model (e.g., economic) to assess the outcome of each scenario. The PRA method, which was originally designed on the basis of the technical performance of components, can be extended as shown further to include human and organizational factors. In a different form, the same approach can be used to address environmental problems [22] and to examine other types of systems involving human networks and organizations. Risk analysis can then be combined with game theory to assess for instance, the risk of an attack when intelligent actors are involved [23,24].

Objectives of PRA

PRA has two main purposes: to optimize resource allocation (e.g., to minimize the probability of system failure given budget and schedule constraints) and to check that the failure risk is tolerable. Proactive risk management requires recognizing, anticipating, and correcting problems before an accident occurs. PRA allows improvement of both system design and operations by setting priorities among risk reduction measures, while accounting for costs, benefits, and uncertainties about them [25]. Clearly, such decisions also require a value judgment; for instance, what costs are justified by a given decrease of the failure risks, or what level of failure probability is tolerable given that few risks can be reduced to zero unless the hazard is eliminated altogether [26–28].

Therefore, one of the major functions of a risk analysis is to represent uncertainties in risk management decisions, especially for systems that are poorly known or when failures are rare. These uncertainties can be treated at different levels of complexity [29]. What is described here is a PRA method that generally yields a distribution of the

⁵For example, a complete risk analysis has been performed for the International Space Station ([20]).

⁶It is such a heat shield failure that eventually caused the accident of the Columbia orbiter in 2003.

outcomes by their complementary cumulative distribution.⁷ Such a risk curve can then be used as input in a single-attribute decision analysis [30] in the framework of rationality defined by the von Neumann axioms [31]. The result can also involve several dimensions (monetary losses, human casualties, and environmental damage). The result of the PRA can then be represented by a surface, which becomes an input in a multiattribute decision analysis [32].

Risk assessment is not a static exercise. It represents the state of knowledge about a system state at a given time, but the result may change, either with additional information or with changes in the system (improvements or deterioration). Therefore, to be useful, a PRA must be a “living document,” updated as more information becomes available.⁸ In that respect, warnings and precursors play an essential role. Observing and interpreting precursors and signals of defects or malfunctions are essential in guiding both risk assessment and risk management [34]. This involves integrating occurrences and observations of these precursors, updating the probabilities of the corresponding failure modes or accident sequences, and taking timely corrective measures.

Organization of This Article

This article describes and illustrates the PRA method and some of its extensions. First, the notion of probability and the fundamental rules of probability computation are presented. The next section describes the basic tools of PRA: events trees, fault trees, and functional block diagrams. The PRA process is then described and illustrated by several examples including the risks of subsystem failures in nuclear reactors and oil spills caused by loss of propulsion of oil tankers.

⁷The complementary cumulative distribution of a random variable shows the probability of exceeding different loss levels. These risk curves are sometimes called “Farmer risk curves” [33].

⁸Note that more information does not always imply a reduction of uncertainty. This occurs for example, when experience shows that the prior probability (assessment *a priori*) was way off base.

The dynamic aspect of accident sequences is illustrated by the case of patient risks in anesthesia, starting from the initiating event (e.g., a disconnection of the oxygen tubes) and ending with the recovery—or not—of a patient who cannot live when deprived of oxygen for more than a few minutes [35]. In many cases, the main challenge was in the formulation of the problem; that is, which variables and relationships to consider, dynamic representation, economic analysis, and so on.

PROBABILITY AND SOURCES OF DATA

As mentioned earlier, failure probabilities can be based on two different definitions: the classical statistics interpretation based on the frequency of an event in a sufficiently large sample, and the Bayesian approach, which relies on the degree of belief of a decision maker or a risk analyst. Bayesian probabilities are obtained by considering first, the prior probability of an event, a state or a hypothesis before additional information is acquired, then by updating this prior with new data. This is done, as shown further, by combining the prior probability with the likelihood of a new piece of information (probability of obtaining these data given the state of interest) to obtain a posterior (updated) probability of that state.

It is important to note that the Bayesian definition of probability allows using all relevant information, not only statistical data when they exist, but also expert opinions. The Bayesian method has been used, for instance, in the nuclear power industry for parameter estimation [36].

Fundamental Rules of Bayesian Probability Computation

Two laws of probability are at the basis of probability computation and in particular, in a PRA context: the total probability theorem and Bayes theorem.

Notations:

$P(A)$ = marginal probability of event or property A ,

$P(A, B) = P(A \text{ AND } B)$: joint probability of A and B ,

$P(A | B) = P(A \text{ GIVEN } B)$: conditional probability of A given B ,
 $P(\text{NOT } A) = \text{probability of NOT } A = 1 - P(A)$.

The *Total Probability Theorem* links the probability of an event A (e.g., system failure) to the probability of the intersection of the set of scenarios containing A with a set of mutually exclusive and collectively exhaustive scenarios B_i that may or may not contain A .⁹ For the simple case where there are only two B_i cases, scenarios B or NOT B , the total probability theorem can be written as

$$P(A) = P(A \text{ AND } B) + P(A \text{ AND } (\text{NOT } B))$$

More generally, for a set of appropriately structured scenarios B_i , the theorem can be written as

$$P(A) = \sum_i P(A \text{ AND } B_i)$$

The *Bayes theorem* links the prior probability of A and the likelihood of B to the obtain the posterior probability of A once it was established that B is true. Consider the case where A is a particular hypothesis and B a signal or some type of observation.¹⁰ $P(A)$ is the prior probability of A , $P(A | B)$ is the posterior probability of A once B has been observed. $P(B | A)$ represents the likelihood of observing that signal if A is true (or about to happen). The Bayes theorem can be written as

$$P(A | B) = P(A, B) / P(B) = P(A) \times P(B | A) / [P(B, A) + P(B, \text{NOT } A)]$$

This formula permits computing, by expansion, the probability of a scenario involving A and B as the joint probability of these

two components.¹¹ It allows, in particular, accounting for dependencies among A and B represented by $P(A | B)$ or by $P(B | A)$. Only in the case where A and B are independent, can one write that $P(A | B) = P(A)$ and therefore, $P(A, B) = P(A) \times P(B)$.

The same formula applies to a scenario involving more than two variables or events, for example, A and B and C and D . The Bayes theorem permits computation of this scenario as the joint probability of A , B , C and D expanded as

$$P(A, B, C, D) = P(A) \times P(B | A) \times P(C | A, B) \times P(D | A, B, C).$$

Two Kinds of Uncertainties

It is sometimes assumed that probability simply represents the randomness that one may observe through a statistical sample. In reality, uncertainty encompasses aleatory uncertainty (randomness) and epistemic uncertainty that reflects one's lack of knowledge about fundamental mechanisms or phenomena [37]. PRA may involve both, in which case the results may be represented not only by a single risk curve (combining both types of uncertainties) but by a family of risk curves separating both in the display of results [38]. In any case, both types of uncertainties can be described by Bayesian probability, which is the basis of the methods of risk assessment presented here.

One main problem is to assess the different probabilities that are the input of a PRA [39]. In what follows, it is understood that one can use classical statistics to generate data about the different parts of the problem and rely on observed failure frequencies of various components when that information is available. This requires samples of sufficient size and failure mechanisms that are stable enough over time so

⁹For instance, if A represents a system's failure, the probability of A is computed as the sum of the probabilities of all scenarios containing A , provided these scenarios do not overlap and cover all possibilities.

¹⁰ A can be a system's failure and one may want to compute the probability of A given that a crack has been observed in one of its critical subsystems (B).

¹¹Note that the order in which A and B are introduced does not matter because $p(A \text{ AND } B)$ is equal to $p(B \text{ AND } A)$. Therefore, the Bayesian formula as written here is equivalent to $P(A, B) = P(A) \times P(B | A) = P(B) \times P(A | B)$.

that past statistics provide adequate probability estimates. Often however, it is not the case by, for example, for new systems. The Bayesian approach then allows using all relevant information including test data and surrogate data that are collected in similar but not identical settings, and have to be updated to accurately represent the phenomenon of interest in actual operations. Relevant information also includes expert opinions, that is, subjective degrees of belief from specialists of the different parts of the system, which the analyst adopts based on his or her confidence in the expert.

Expert Opinions

In the Bayesian framework, expert opinions play a critical role, among other things because they allow assessing epistemic uncertainties since by definition, one does not have statistical frequencies to represent them. The opinions of experts reflect their experience but may be distorted by cognitive biases [40,41] as well as a desire to influence the risk management decision. The likelihood function that is used to include an expert's opinion in the updating of a prior probability thus reflects the confidence of the analyst in the judgment of the expert.

Problems arise when using the opinions of several experts who disagree. The analyst then faces the challenge of aggregating these opinions to generate PRA inputs. This can be done by simply weighting the expert opinions in a linear aggregation function to obtain the probability of interest. A more sophisticated approach is to use a Bayesian analysis, which allows accounting for possible dependencies among the opinions of different experts who may share for example, the same fundamental model about the variable of interest [42,43]. This approach requires the use of probabilities (likelihoods) that represent not only the confidence of the analyst in each expert, but also the analyst's assessment of dependencies among the opinions of the experts.

The aggregation of expert opinions can also be done by an iterative process such as the Delphi method, in which each expert is asked to provide an estimate of a probability, the results are then aggregated by the

analysts and sent back to the experts who are given an opportunity to revise their individual judgments. These adjustments can be reiterated until the process converges [44]. Another approach is based on direct interactions among experts, which permits explicit elicitation of mental models, exchange of experience, and comparison of information bases, in order to come up with a collective estimation. This was done in the case of seismic risk analysis by Budnitz *et al.* [45].

The use of expert opinions introduces an element of subjectivity in a Bayesian analysis. The question is—what are the alternatives? In the absence of a systematic analysis, the same element of subjectivity would exist, but at a higher level of analysis, where the information base and the level of experience may be much thinner. Instead, decomposing the problem into different parts allows using the experience of the most qualified experts in the different fields involved. For example, when assessing seismic risk for a given structure, the problem can be decomposed between seismic hazard, which is the speciality of seismologists, and buildings' vulnerability which is in the domain of structural engineers. In general, the result is thus better informed than a direct subjective assessment of the failure risk.

Using all these sources of information and data, the role of the analyst is to support a decision by representing uncertainties about all variables and events (including experts' dissents) as accurately as possible and as free of value judgment as can be achieved. It is then the role of the decision maker to include his or her risk attitude in the risk management decision to be made.

BASIC TOOLS OF ENGINEERING RISK ANALYSIS: EVENT TREES, FAULT TREES, AND FUNCTIONAL BLOCK DIAGRAMS

The PRA process involves identification of the failure scenarios (conjunctions of events leading to failure) and computation of the probabilities and consequences of these scenarios. Two fundamental tools used in that process are event trees and fault trees. Event trees permit systematic identification and

structuring of the set of possible scenarios so that they are collectively exhaustive (all possibilities are included) and mutually exclusive (each scenario appears only once in the tree). Fault trees permit identification of the scenarios (conjunctions of component failures) that lead to system failure. In complex systems, the first question is—what functions must be performed for the system to work? This is described by functional block diagrams.

Event Trees

Event trees represent a systematic identification of possible scenarios, which are conjunctions of uncertain events and/or random variables. These may include component failures as well as external events such as waves, winds, or earthquakes that affect the probability of failure of components or subsystems. The structure of a generic event tree is shown in Fig. 1.

The tree is read from left to right. The circles represent chance nodes corresponding to an event or a random variable. Each chance node is followed by branches representing

the possible realizations of that chance event or variable (e.g., the subsystem succeeds or fails). On each branch, one places the probability of that realization of the chance node given everything else that precedes it in the tree. A “path” (or scenario) is a set of branches that link the original event to a possible outcome (e.g., overall system failure or success). Event trees thus provide a simple way of representing both the scenarios and the dependencies among events. Figure 1 includes three chance nodes, A , B , and C . The probability of each scenario (hence the probability of the corresponding outcome) is simply the product of the conditional probabilities along the corresponding path. For example, the probability of the path or scenario (A , NOT B , C) is

$$P(A, \text{NOT } B, C) = P(A) \times P(\text{NOT } B | A) \times P(C | \text{NOT } B, A).$$

The structure of an event tree is thus determined by conditional probability. Its elements are not necessarily displayed in chronological order, even though it is often

Figure 1. Representation of an event tree including three binary events A , B , and C (for example, A : initiating event; B : intermediate development; C : final system state, and O : outcome such as the amount of a product spilled in the environment as a result of system rupture).

Figure 2. Event tree to compute the risk of ship grounding due to loss of propulsion. (Source: Paté-Cornell [11].)

a convenient way to build the tree. Instead, the order of the variables may be adapted to fit that of the available information.¹² At the end of each path, the scenario's outcome is displayed, whether it represents a system's failure or decreased performance. The consequences can be financial, health-related, or environmental.

An example of an event tree in a risk analysis is shown in Fig. 2. That simplified event tree can be used to compute the risk of an oil spill due to loss of propulsion, LOP, of an oil tanker. The simplified scenarios are the following. If a tanker loses propulsion, it may start drifting depending on external factors (currents, tides, winds etc.) and on the skill of the crew to control the drift. If it is close to the sea floor or obstacles (e.g., rocks), the risk may be grounding, which can cause a breach (of different possible sizes) in the hull. At that point, various amounts of oil can be released into the sea.

Figure 2 thus shows both discrete events (LOP; drift control, CD or not, UD, and grounding of the ship G), and continuous random variables (the size of the breach in the hull, B , and the amount of oil spilled in the sea, O). The discrete random variables

are characterized by their marginal and conditional probabilities. The size of the breach in the ship hull is characterized by its probability distribution function, conditional on drift control, and grounding (realizations of B are noted b). The amount of oil spilled in the seawater is the result of that event tree. It is characterized by its probability distribution conditional on the breach size. Its overall (marginal) probability distribution is obtained by summing the probabilities of oil spilled for all breach sizes.¹³ Further analysis of the consequences (not shown here) allows quantifying the probability distribution of associated losses.

In the case of ship grounding, the sequence of events leading to failure is relatively straightforward. It is not necessarily the case for complex systems involving multiple redundancies. What an event tree does not always show is whether or not a conjunction of component failures causes the whole system to fail. That information can be provided by a description of the functions that the system must perform to work and by fault trees, which use that information to derive the sets of component failures leading to failure of the whole system.

¹²For instance, it may be convenient to place A followed by B (in the tree) if one can assess directly $P(A)$ and $P(B|A)$. But if $P(B)$ and $P(B|A)$ are easier to assess, the order may be B followed by A .

¹³The amount of oil spilled in the sea water (in this case) can also be referred to as the "source term."

Figure 3. Functional block diagram for a system of two subsystems in series *A* and *B*, the second one (*B*) composed of two components in parallel, *B1* and *B2*.

Functional Block Diagrams

Sometimes called “reliability block diagram”, functional block diagrams represent the main functions to be performed for the system to work and the corresponding subsystems in series. For each of these main functions, the diagram then includes the components or subsystems that can perform the function. Each function can then be analyzed according to its structure (components in series or in parallel); for example, whether or not each function involves redundancies. Figure 3 represents as an illustration, the functional block diagram for a power supply system that requires both DC and AC power for the system to work. That system is composed of one DC power supply and two redundant AC power buses. The system shown here fails either if component *A* (DC power) fails or if subsystem *B* (AC power) fails, which requires that both redundant components *B1* and *B2* fail.

Fault Trees

A fault tree represents the logical relationship between the failure of a system and the failures of its subsystems and basic components. It is a snapshot showing how the state of the system depends on the state of its components. It is composed of a set of logical Boolean functions (for instance, OR gates and AND gates as shown below in Fig. 3) whose inputs and outputs are Boolean (0 or 1) variables.¹⁴

Figure 4 shows two examples of fault tree functions (“gates”). The top one (“OR gate”) represents the logical link between the failure of a system ($B = 1$) and that of its components in the case where $B = 1$ if any of the three inputs A_1, A_2 , or A_3 are equal to 1. This function represents the case of a system (*B*) of three components in series (A_1, A_2 , and

¹⁴ $X = 1$ means here that component *X* is in a failed state.

Figure 4. Logical (OR and AND) gates in a fault tree.

A3) so that the whole system B fails if any of the A's fail. On the right-hand side of the tree, the figure shows several notations used to represent that OR function¹⁵:

$$B = A1 \text{ OR } A2 \text{ OR } A3;$$

$$B = A1 + A2 + A3;$$

$$B = A1 \cup A2 \cup A3,$$

which means that B represents the unions of all sets of scenarios including A1, A2 or A3.

The bottom part of Fig. 4 represents the logical link between the failure of a system ($B = 1$) that occurs if all of the three inputs A1, A2, or A3 are equal to 1; that is, B fails if all of the three components A1, A2 and A3 have failed. This function represents the case of a system (B) composed of three components in parallel (A1, A2, and A3) such that the whole system B fails if all three redundant elements A1 and A2 and A3 fail. Again, on the right-hand side of the tree are several notations used to represent the function¹⁶:

$$B = A1 \text{ AND } A2 \text{ AND } A3;$$

$$B = A1 \cdot A2 \cdot A3$$

$$B = A1 \cap A2 \cap A3,$$

which means the intersection of A1, A2, and A3.

The fault tree corresponding to a particular system is derived from its functional structure as described by its functional block diagram. For a system of elements in series to work, all the elements must work. For a system of elements in parallel to work, at least one of the (redundant) components must work. The system or subsystem thus fails if any of its basic functions in series are not performed, or if all of its elements in parallel have failed. Boolean algebra allows

writing and simplifying the logical equations represented by a fault tree. A Boolean polynomial made of the Boolean functions shown in Fig. 3 can be written based on the fault tree to represent the “top event” (output of the fault tree) as a function of the basic events (inputs of the tree).

A fault tree is generally constructed top-down, in a deductive manner, starting with the failure of the whole system. The failure event is then decomposed into failures of subsystems and components in parallel (AND gate) and/or in series (OR gate) according to the structure of its functional block diagram. Figure 5 shows a fault tree corresponding to the power system represented in Fig. 3 whose role is to provide power to the emergency safety features (ESF) of a reactor. Figure 5 (which can be read from top to bottom) indicates that the system fails if there is no AC power or no DC power (event A), and that for AC power to fail, there must be loss of power from both on-site (event B1) and off-site (event B2) buses. The top event (main failure) is the loss of power to ESF.

Fault trees and events trees are often used together in technical risk analyses. The structures of the model and its submodels, involving the identification of all possible classes of scenarios, showing their probabilities and their consequences, are represented by event trees. Fault trees, based on functional block diagrams, are used to identify the scenarios that lead to system failures and to compute the probability of failure of the whole system. That information can be direct input into an event tree, which can include in addition, external events, human errors and other factors that affect component failure probabilities.

THE PRA PROCESS AND RESULTS

The PRA process is a systematic way to identify a system's failure modes and quantify its failure risks. The first step is to identify the functions involved in the system's operations, and the set of scenarios that may follow an “initiating event” triggering an

¹⁵The OR function, represented by the + sign in Boolean algebra, is such that $1 + 1 = 1$, $1 + 0 = 1$, and $0 + 0 = 0$.

¹⁶The AND function in Boolean algebra represented by the $\times$ sign, is such that $1 \times 1 = 1$, $1 \times 0 = 0$, and $0 \times 0 = 0$.

Figure 5. Fault tree for the failure of the power supply of an emergency system (ESF: Emergency Safety Feature). (Source: USNRC [5].)

accident sequence.¹⁷ As mentioned earlier, to be amenable to probabilistic analysis, these classes of scenarios have to be structured logically (beyond simple “what if?” questions) so that they are mutually exclusive and collectively exhaustive. The second step involves computation of the scenarios’ probabilities, including external events that can affect the probabilities of basic failures. The third step is to assess the scenarios’ consequences, including the different attributes relevant to the decision; for example, the effects of system failures on human safety, monetary results, and environmental damage. The results can be presented as a single risk curve if the inputs of the PRA are the probabilities of events and distributions of random variables. The analysis can be performed at a second level of uncertainty analysis, which involves uncertainties in

the future frequencies of component failures and the results of these uncertainties on the overall failure probability.

First Level of Uncertainty Analysis: A Single Risk Curve

Given a specified engineered system, the PRA process often starts with a functional block diagram. The functional block diagram can then support the construction of a fault tree. One can derive from that fault tree the failure modes or “minimal cut sets”, that is the minimum sets of component failures leading to failure of the whole system.¹⁸ To compute the probability of each type of scenario, one can use event trees (or their equivalent) especially in the case where external events and loads are involved in failure probabilities. As described earlier, these scenarios represent the conjunctions of events defining

¹⁷The choice of a level of detail is critical to the feasibility of the analysis. Very detailed scenarios add complexity that is not always useful. Instead, the issue is to decompose the problem into classes of scenarios that are manageable, and for which one can identify clearly the relevant information. The appropriate depth of analysis may vary across the subsystems; for instance, more details may be required in places where there is little operational experience.

¹⁸Note that fault trees involve Boolean variables (1 or 0) that represent functional failure (or not) of each component. In their classic form they do not include partial failures in which the component may not work perfectly but still well enough for the system to function.

Figure 6. Risk curve and family of risk curves representing the results of first and second levels of uncertainty analysis in a PRA.

each scenario and allow computing the corresponding joint probability.¹⁹

Fault trees and event trees, as illustrated further for a nuclear power system, are thus fundamental tools of the PRA method; the former relying on logic functions and the latter on conditional probability [46]. Finally, specific consequence models (e.g., dispersion analyses, dose-response analyses, economic analyses) are needed to assess the outcomes of system failures (partial or total). When the consequences of the different scenarios have been assessed, the results can be displayed as a probability distribution (density function) of the losses per time unit or operation. Alternatively, they can be represented as a cumulative distribution function or its complement; that is, a risk curve that shows the probability of exceeding different loss levels in a given time unit (see left-hand side of Fig. 6).

¹⁹Fault trees and event trees can be considered roughly equivalent, although fault trees represent logical functions and event trees represent exhaustive sets of scenarios (including failures or not) and are based on marginal and conditional probabilities. The main difference arises when external events are involved. They are not part of failure modes but affect the probability of failure of components. They are thus best handled by event trees.

The main characteristic of this process is to be systematic and rational according to the classic criteria of von Neumann [31]. It also allows accounting not only for uncertainties, but also for dependencies among failures. Dependencies can arise for example, when failure of one component puts a higher load on a redundant one, or when an external event (e.g., an earthquake) applies simultaneous loads on several components. Dependencies can also be caused by a common manufacturing process or an operator error that affect several components.

Second Level of Uncertainty Analysis: A Family of Risk Curves

A second level of analysis may be required to represent uncertainties about the input; that is, about the future failure rates of basic components. This is needed if the decision maker is sensitive to uncertainties about the failure probabilities [47]. Also, in many cases, the analysis is done for one system per time unit. The second level of uncertainty is needed to extend that analysis to several identical systems for several time units [48]. This requires propagation of uncertainties through the PRA and representation of these uncertainties in the result [38].

Uncertainties about future failure frequencies can sometimes be characterized by lognormal distributions. If these variables

are multiplied in the analysis, the product is also lognormal yielding a closed-form solution. Also, uncertainties about the probabilities of basic events can be represented, for instance, by beta distributions. In most cases, one has to simulate the propagation of uncertainties about basic event probabilities throughout the PRA model to represent their effects on a distribution of the overall system failure probability, or on the probability of exceeding different loss levels per time unit. The risk analysis result is then a family of risk curves (right-hand side of Fig. 6). Each curve represents a fractile (e.g., 10%, or 95%) of the probability distribution of the chances of exceeding various levels of losses in a given time period or operation [38]. In Fig. 6, the meaning of $P_1(x)$ is that there is a probability 0.95 that $P(X > x)$ is less than P_1 , or, $P[P(X > x) < P_1] = 0.95$. The meaning of P_3 is that there is a probability 0.05 that $P(X > x)$ is less than P_3 . What follows in this article is limited to the first level of uncertainty analysis, resulting in a single risk curve.

EXAMPLES AND ILLUSTRATIONS FROM THE NUCLEAR POWER INDUSTRY

Different Models That Need to be Combined

The general model of the risk of failure of nuclear reactors (and of many other systems that can release toxic or polluting material) can be described as a combination of submodels as shown in Fig. 7.

Note that this model structure applies with only minor modifications to many other cases. For example, submodel #3 as shown in Fig. 7 yields the amount of fission product released in the atmosphere in the case of a nuclear reactor or toxic substance released in the case of a chemical plant. This amount released (“source term”) often depends on the final state of the system. In nuclear reactors, it can be characterized (among other factors) by the damage to the containment structure. In the case of grounding of an oil tanker, this final system state can be described by the size of the breach in the hull, the source term is the quantity of oil released in the sea, and the “dose-response” relationship describes the health and environmental damage associated with the oil spill.

The two following examples (both from a risk analysis for nuclear reactors) illustrate the tools and the process described in the previous sections. First, the risk posed by the possibility of a steam-generator pipe rupture is used to show the structure of a risk analysis model involving both event trees and fault trees. Second, the failure risk of an auxiliary feed water system (AFWS) illustrates the use of functional block diagrams to identify failure modes and compute their probabilities given the possibility of external events such as earthquakes.

Example 1. Steam-generator pipe rupture. In this example (from the Reactor Safety Study [5]), the initiating event that can start an accident sequence is a feed

Figure 7. The different models of a nuclear PRA. (Source: USNRC [5].)

Figure 8. Event tree for steam generator pipe rupture. (Source: USNRC [5].)

water pipe rupture in the steam generator. Steam generators are heat exchangers used in pressurized water reactors to generate electricity. They are at the interface between the primary (radioactive) coolant loop that goes through the nuclear reactor core, and the secondary (nonradioactive) coolant loop that delivers steam to the turbines. The integrity of these pipes is critical to prevent radioactive steam from contaminating the rest of the system. To be able to face such a loss-of-coolant accident, nuclear reactors are equipped with an emergency core cooling system, which requires electricity. If radioactive material is released in the containment structure, an emergency safety feature is in place to remove fission products. Finally, a (secondary) containment structure sits over the whole reactor as a barrier to the release of radioactive material in the atmosphere.

As discussed earlier, the general structure of this model relies first on event trees that collectively represent an exhaustive, mutually exclusive set of failure scenarios following (in this case) an initiating event, then on fault trees, to compute the probabilities of the scenarios that lead to system failure.

Figure 8 represents the event tree that can be used to compute the probabilities of the different scenarios (i.e., the paths from the initiating event to the different outcomes) that can follow a steam-generator pipe rupture (event A). If one of the steam-generator pipes breaks, the regular water flow does not cool the core anymore. The emergency core cooling system then kicks in, provided that electric power is available (electric power failure: event B) and the emergency cooling system itself works (failure: event C). If it does not, radioactive material may be released inside the containment structure, and removed by an emergency fission product removal (failure: event D). If that does not work, the containment structure itself may prevent the radioactive material from contaminating the atmosphere. If that structure does not hold (event E), the radioactive material is released into the environment (failure F). The probability of each scenario is the product of the marginal probability of the initiating event and of the conditional probabilities along the path.

The lowest branch in the tree shown in bold in Fig. 8 involves the loss of containment

Figure 9. Functional block diagram for an auxiliary feed water system in a nuclear reactor. (Source: Cornell and Newmark [49].)²⁰

integrity. It represents the only scenario that leads to system failure F (release of radioactive material in the atmosphere) following the initiating event “steam-generator pipe rupture” (A). That failure scenario includes the loss of containment after all other emergency systems failed (B , C , and D) following the initiating event A . The failure probability associated with that particular initiating event is that of this last scenario (using Bayes theorem as shown earlier); that is,

$$P(F) = P(A) \times P(B | A) \times P(C | A, B) \\ \times P(D | A, B, C) \times P(E | A, B, C, D).$$

The probability of failure of each subsystem can, in turn, be calculated separately. For example, the probability of failure of the power system can be estimated through a fault tree such as the simplified one that was shown in Fig. 5.

The Case of the Auxiliary Feed Water System (AFWS) of Nuclear Reactors

The AFWS of a nuclear reactor is called upon when the main cooling system is not functioning. The structure of that system is represented by a simplified functional block diagram shown in Fig. 9 as comprising

two subsystems in series: water storage and pumps. In this illustration, the AFWS involves two storage tanks in parallel, and two pumps in parallel, a turbine pump, and an electric pump, which requires energy from a generator.

The fault tree for this simplified AFWS can be represented as shown in Fig. 10 (although this representation is not unique). From that fault tree, one can identify the failure modes (or minimal cut sets); that is, the minimum sets of component failures that would lead to the failure of the AFWS. To do that, one generally uses a Boolean representation of the fault tree. Calling A , B , C , D , E , the Boolean variables that represent failure (or not) of the different components shown in Fig. 9, the

Figure 10. Fault tree for the AFWS shown in Fig. 9. (F : failure of the system).

²⁰Note that in such a diagram, the lines do not represent physical elements such as pipes or wires but the structure of the systems and subsystems.

Boolean expression that links the failure of the system ("top event" F) to those of the basic events is as follows (after application of some Boolean laws of logic):

$$F = (C \text{ AND } D) \text{ OR } (C \text{ AND } E) \\ \text{OR } (A \text{ AND } B).$$

The three failure modes (M_i) are thus C AND D (M_1 : loss of turbine pump and generator), C AND E (M_2 : loss of turbine pump and electric pump), and A AND B (M_3 : loss of both water tanks). The first two failure modes (M_1 AND M_2) imply that both pumps are off, and the last one (M_3) that no water is available.

One can then assess the probabilities of the different failure modes and combine them to compute the overall probability of failure of the AFWS accounting for failure dependencies, such as a failure of the two water tanks.²¹ For example, the probability of M_3 (failure of both water tanks) is

$$P(M_3) = P(A) \times P(B | A) = P(B) \times P(A | B).$$

Only in the case where A and B are independent events, can the probability of M_3 be written as $P(A) \times P(B)$.

Following the total probability theorem described in the section titled "Probability and Sources of Data," the probability of failure of the whole system is

$$P(F) = P(M_1) + P(M_2) + P(M_3) \\ - P(M_1 \text{ AND } M_2) \\ - P(M_1 \text{ AND } M_3) - P(M_2 \text{ AND } M_3) \\ + P(M_1 \text{ AND } M_2 \text{ AND } M_3).$$

External Events

The example of the AFWS has been used in the literature to illustrate the effect of external events such as earthquakes on the performance of a system [49]. External events

must be included in PRA, separating on the one hand the probability that they occur and the severity of an event if it occurs (hazard analysis) and on the other hand, the probability of system failure (fragility) given an event's severity. Hazard analysis thus represents the uncertainty on the loads and fragility analysis, the uncertainty about the capacity, which is the maximum load that the structure can withstand.

Loads and capacities are often measured on a continuous scale (e.g., the peak ground acceleration of an earthquake). Note their density distribution functions $f_L(x)$ and $f_C(x)$ respectively, and F_L and F_C the corresponding cumulative distribution functions, in which the probability of the load is estimated for a given time period (e.g., a year). The probability of failure during that time unit is the probability that the load exceeds the capacity or that capacity is less than the load:

$$\left\{ \begin{array}{l} P_F = \int_X f_L(X) F_C(X) dX \\ \quad = P(L = X \text{ and } C < X) \\ \text{or} \\ P_F = \int_X f_C(X) G_L(X) dX \\ \quad \text{with } G_L(X) = 1 - F_L(X) \\ \quad = P(C = X \text{ and } L > X). \end{array} \right.$$

Knowing the probability distributions of loads and capacities through experience in operations, tests, engineering models or expert opinions, one can compute the overall probability of a system's failure accounting for occurrences of external events, their effects on the components, and the resulting failure dependencies.

An Overarching Analytical Framework for Risk Analysis Based on "Pinch Points"

The different models that yield the probabilities and consequences of different accident scenarios need to be combined to obtain an overall assessment of the failure risk. One way of doing so is to structure the analysis as a product of state vectors and transition matrices in an overarching model as represented in Fig. 11 for the particular case of a nuclear reactor [50].

²¹This means that knowing that one of the tanks has failed, changes the probability that the other one has too.

Figure 11. Assembly model for nuclear power plants. (Source: Garrick [50].)

This model can be generalized to most systems that present the risk of releasing a pollutant or toxic substance in the environment (e.g., an oil tanker, or a chemical plant). The computation starts with a vector representing the probability of the different initiating events. The risk is then estimated using the models described earlier. The different steps include a sequence of computations: of the probability that the system/plant/reactor ends in different states given the possibility of different initiating events; of the probability that given the plant state and its containment system is compromised to various degrees; of the resulting distribution of quantities released; and of the probabilities of the final states of the site based on environmental models.

This overarching model can be represented by a sequence of products of vectors and matrices that simply reflects the fact that the probability of reaching a given state at any stage is the sum of the probabilities of starting from any possible state in the previous stage and reaching the state of interest in the next stage. The sequence of transition computations is thus the following.

Notations

- *Initiating Events.* Vector $\{IE_i\}$ is the probability of initiating events indexed in i per time unit.
- *Plant (or Final System) State.* Vector $\{PS_j\}$ represents the probabilities of the final system states; that is, of the different end points of accident sequences indexed in j .
- *Plant Model.* Matrix $[PM_{ij}]$ is the set of probabilities of transition from IE_i to PS_j .
- *Source Term.* Vector $\{R_k\}$ is the probability of the release category (released quantity) indexed in k .
- *Containment Model (for Nuclear Reactors).* Matrix $[CM_{jk}]$ is the probability of transition from plant state j , PS_j , to release level R_k .
- *Damage Vector.* $\{D_l\}$ is the probability of loss (or damage) level l .
- *Site Model.* Matrix $[SM_{kl}]$ is the probability of transition from source term k to damage level l .

Assembly Model

1. From initiating events to final plant states: The nuclear power plant risk analysis model (or PRA model of another system of interest, using fault and event trees or similar techniques) yields the probability that an accident that started with initiating event IE_i ends in the final state PS_j . The probabilities of transition from IE_i to PS_j are the elements PM_{ij} of matrix PM , which represents the plant model. They are computed through combinations of event trees and fault trees as described earlier.

$$\begin{aligned}\{PS\} &= \{\tilde{IE}\}[PM] \Leftrightarrow PS_j \\ &= \sum_i IE_i \times PM_{ij}.\end{aligned}$$

2. From plant states to release category: Next, the containment model allows computation of the probability that a plant state PS_j leads to a release category R_k . The probabilities of transition from PS_j to R_k are the elements CM_{jk} of the matrix CM , which represents the results of the containment model.

$$\begin{aligned}\{R\} &= \{PS\}[CM] \Leftrightarrow R_k \\ &= \sum_j PS_j \times CM_{jk}.\end{aligned}$$

3. From release category to site damage: In turn, the site model allows computation of the probability that a release category R_k leads to a level of damage D_l . The probabilities of transition from R_k to D_l are the elements SM_{kl} of the matrix SM , which represents the site model.

$$\{D\} = \{R\}[SM] \Leftrightarrow D_l = \sum_k R_k \times SM_{kl}$$

4. From initiating event to site damage: These three equations can then be combined to link the distribution of the final damage to the probabilities of the initiating events through the different

submodels: plant (system) model, containment model, and site model.

$$\begin{aligned}\{D\} &= \{\tilde{IE}\} \times [PM] \times [CM] \times [SM] \\ \Leftrightarrow D_l &= \sum_k SM_{kl} \\ &\times \left(\sum_j CM_{jk} \left(\sum_i IE_i \times PM_{ij} \right) \right).\end{aligned}$$

Therefore the risk, that is the probability distribution of the damage per time unit or operation, can be computed starting with the probabilities of the initiating events, using the plant model, the containment model, and the site model.

Pinch Point Concept

An important element of the structure of this assembly model is the notion of “pinch point” [50]. This means that what follows in the model only depends on the state reached so far, not on the scenario by which it was reached (e.g., a particular state of the system, which is all that matters to compute the consequences). Therefore, the downstream computations following a pinch point depend only on the state at that particular stage, which allows multiplication of the transition matrices PM , CM , and SM as independent transition models.

This model has wide applications, for example, to assess the risk of an oil spill caused by loss of ship propulsion followed for instance, by an uncontrolled drift in a shallow zone, so that the hull is breached and a quantity of oil is released into the sea. In the end, it is in large part the size of the breach that determines the amount of oil in the sea, not the events that led to that breach.

INFLUENCE DIAGRAMS AND BAYESIAN NETWORKS AS TOOLS TO STRUCTURE A RISK ANALYSIS MODEL

Influence diagrams can represent on one figure the elements of risk analysis and risk management models, and their relationships. Therefore, they are very convenient

Figure 12. Influence diagram: risk of ship grounding and oil release in the sea. (Source: Paté-Cornell [11].)

tools, especially in the formulation phase of such models. Influence diagrams are directed graphs that are essentially homomorphic to decision trees. They explicitly display the probabilistic links among the different variables (decisions, random events, state variables, and scenario outcomes) of a decision analysis model [51]. These variables are represented by nodes (respectively, rectangles, ovals, and lozenges) and the arrows among them represent the conditional dependencies between the variables that they connect. Influence diagrams include not only a graph, but also the numerical tables that represent the realizations of the different variables, their probability distributions conditional on what precedes them in the diagram, and the values of the possible outcome realizations.

Bayesian networks used in risk analysis can be viewed as influence diagrams that do not include decision nodes but only state and outcome variables. These networks/diagrams are resolved by a computer's "inference engine" based on the laws of Bayesian probability. They provide in the end, a probability distribution of the losses that can be incurred given the probabilities of adverse (initiating) events and the models of the system's evolution thereafter.

Ship Grounding

An example of such diagrams represents the risk, as described earlier, of an oil spill as

a result of ship grounding caused by loss of propulsion, LOP.²² The Bayesian network of Fig. 12 represents the same information as the event tree of Fig. 2 (but includes a few more variables). In the same way, it starts with one initiating event: the LOP of an oil tanker. Given that this event has occurred, the weather, and the speed of the boat, the next question (state variable) is whether or not the crew is able to control the drift. Given the drift control, the speed, and the location, the next question is whether grounding occurs and at what energy level. Given that grounding occurs, the nature of the seabed, and the speed, the next variable is the final system state, measured by the size of the breach in the hull. Finally, the breach size and possibly the weather, determine the amount of oil released into the sea [11].

This model, like the event tree presented earlier, can then be used to assess the effectiveness of risk management measures such as requiring double hulls for some types of ships or improving the response to an incident. The next problem is an optimal allocation of risk management resources, which can be formulated either as the minimization of failure probability given a budget, or minimization of a budget to reach a certain level

²²A subsequent site model could be added to the diagram shown here to assess the damage given the total amount of oil released and the local conditions at the site location.

of safety. These computations require data such as risk/cost functions, linking the reduction of the probability of component failure to the costs involved.

Influence diagrams and Bayesian networks are useful as computational tools, but also an effective means of communication, first with the experts at the onset of the analysis to structure the problem and in the end, with the decision makers, to communicate the results and explain how they were obtained.

The Space Shuttle Heat Shield

In the space shuttle study, an influence diagram was also key to the problem formulation. The objective was to compute the contribution of the black tiles that protect the underside of the orbiters against heat loads at reentry [17]. There are about 25,000 tiles on each orbiter, each different and subjected to different loads according to its location. Each tile is bonded to a felt pad, itself glued to the aluminum surface. The concern is that a tile can debond in flight, creating a gap in the heat shield, and that the turbulence in the tile cavity at reentry could cause adjacent tiles to debond, melting the aluminum and causing loss of critical system functions. After each flight, the tiles are inspected and replaced if necessary; this requires careful cleaning of the cavity and positioning of the tile.

There are two main causes of debonding of the tiles: under normal loads (vibrations, heat, aerodynamic forces, etc.) because

of a weak bond, or under the impact of debris either external (e.g., micrometeorites) or internal to the system (e.g., pieces of insulation of the external tank).

Figure 13 represents the influence diagram showing the structure of the PRA model that was developed for this case. Following one of two possible initiating events (debonding under the impact of debris, or for other reasons such as a weak bond under normal loads), a first tile may be lost. After that, depending on the aerodynamic forces and the heat at reentry at its location, additional tiles may be lost. Under the heat loads at reentry in the atmosphere, a hole may appear in the aluminum structure ("burnthrough"). Hot gases then penetrate the structure causing a subsystem malfunction, which in turn, can cause the loss of the shuttle (orbiter and crew).

The probabilistic computations involved the values of four parameters that varied depending on the location on the surface: heat load, aerodynamic forces, density of debris hits, and criticality of the subsystems under the orbiter skin. The surface was thus partitioned into 33 zones that were characterized by these parameter values as a function of the location. The results were that the tiles contributed to about 10% of shuttle mission failure risks. They also involved a map of the orbiter showing the criticality of the tiles in different locations. It turned out that 15% of the tiles were the source of about 80% of the risk. The challenge was in the formulation of the model using both, the influence

Figure 13. Influence diagram for a risk analysis of the loss of a space shuttle due to tile failure. i : index of min-zones, that is, tile location on the orbiter surface. (Source: Paté-Cornell and Fischbeck [17].)

diagram shown in Fig. 13 and the partition of the orbiter surface into zones of similar characteristics.

EXTENSIONS OF THE CLASSIC PRA MODEL

The PRA models as described above can be extended in several ways to better represent the realities of a system's behaviors for example, the dynamics of accident sequences and system deterioration, or the effects of human and organizational factors. The method can also be extended to other non-technical problems (e.g., an analysis of the risk posed by some human groups) that can be addressed through systems analysis and probability. Again, this systems analysis approach is most useful when relevant statistics do not exist because they involve events or conjunctions of events that are rare or have not occurred before, and when the problem is too complex to be processed directly by the human mind.

Evolution and Deterioration

The evolution (generally deterioration) of the components of a technical system can be represented by different stochastic processes, a simple one being a Markov model, which assumes that there is no memory in state transition and that the time to transition to another state is exponentially distributed. Consider for example, the case of imperfect inspections, after which there is a nonzero probability that the system is in an undetected deteriorated state. The inspection can be described by the distribution of the possible states after such an inspection. One can represent the deterioration of the system by the probability of transition from one state of deterioration to the next, then to failure. The results can then be used to assess the distribution of the time to failure following an inspection, and to decide on an optimal maintenance schedule.

The Dynamics of Accident Sequences

Assessing the dynamics of an accident sequence following an initiating event involves computation of the probability (per

time unit) of transition from each event to the next in each accident sequence. An example of such a dynamic risk analysis model was a study of patient risk under anesthesia [52]. Time is a critical element because the final state of the patient depends on the duration of oxygen deprivation. Following an initiating event, the subsequent steps involve observation of a signal that the event has occurred (e.g., patient reaction); detection, diagnosis, and remediation of the problem; and outcome to the patient (recovery, brain damage or death). For example, following a disconnection of the breathing tube, the oxygen no longer flows and the first signal observed might be that the patient turns blue. The attendants have to observe the signals and the disconnection, then reconnect the tube. The outcome of such an incident is determined by the total time that elapses between the initiating event and the end of the episode.

In this study, a Markov model was used to represent the dynamics of accidents. Partial statistics (e.g., about initiating events and overall mortality rate) allowed calibration of the model. The results included first, the risk of an anesthesia accident per initiating event; second, how this risk could be linked to the "state of the anesthesiologist" characterized in terms of competence and alertness; and third, how a change of management practice (e.g., mandating periodic recertification) affecting the performance factors could reduce the patient risk. It was found for instance, that periodic recertification of practitioners and improved supervision of residents could significantly reduce the risk to the patient.

This dynamic model can be generalized to represent different evolution paths of an accident sequence, the deterioration of various components, and the corresponding changes of the failure probability of the whole system. The results can be used to decide for example, an inspection and maintenance schedule.

Human and Organizational Factors

Human errors are a common cause of system failure, some rooted in personal behavioral problems such as distraction, some in management issues such as an

inappropriate incentive system [53]. Human reliability analysis has been the subject of a whole field of research focusing on both, the causes of human errors and on best practices to eliminate the risks that they pose. In the nuclear power industry for example, Swain and Guttman [54] estimate the rates of human errors that are part of failure modes in the Handbook of Human Reliability using the THERP method (Technique for Human Error Rate Prediction). Kolaczowski *et al.* [55], show for example, the influence of organizations on performance-shaping factors, error mechanisms, actions, human failures, and “unacceptable outcomes.” They use as an example, the 1982 Air Florida crash in Washington DC. In the nuclear power industry, although the two events were of a very different nature, they show common cognitive problems between the Three Mile Island and Chernobyl nuclear accidents. They point in particular, to the fact that in both cases, the lack of operators’ understanding of the basic physics involved led them to ignore instrument readings and field reports. Gertman [56] focuses on performance-shaping factors in the nuclear power industry based on the standardized plant analysis risk human reliability analysis (SPARH), which is designed to encompass all factors that may influence human performance. Bley [57] links the occurrence of human errors to the context of human operations, and the challenges that it sometimes presents, as critical to the probability of an error.

The goal of introducing human and management factors in PRA is to identify and assess possible risk mitigation measures that are human in nature—such as a change in the incentive structure for the operators—as opposed to technical modifications such as adding redundancies to the system. The link between human performance and system reliability can be modeled in several ways. One is to relate the system’s failure risk to the management factors that influence operators’ behaviors. This requires linking the technical elements of the system’s risk analysis (submodel S) to the immediate decisions and actions of the operators (or pilots, anesthesiologists etc.) (submodel

A), and in turn, to link these actions to management decisions (submodel M) in what we call the SAM model [58].

Figure 14 represents the integration of these three levels into a SAM model for the simplified model of ship grounding presented earlier. The lower part (Level 1: starting point of the model) is the technical risk analysis shown in Fig. 12. The intermediate level represents the actions of the maintenance crews as well as those of the ship’s captain and crew in case of a propulsion problem. They include human errors but also, regular and exceptional decisions that may save the system in difficult circumstances. This second level is represented here as a model of random variables, whose realizations and distributions are estimated from the point of view of the decision makers, that is the managers.²³ The third level represents the management decisions that affect the actions of operators at the intermediate level. Organizations provide the structure, procedures, and culture within which employees operate and make decisions. Managers decide how to allocate their resources (e.g., how much should be dedicated to maintenance). In general, they select and train employees, set incentives, and provide information to operators.²⁴

The SAM model has been used for instance, to examine the effect of some organizational factors on the risk of failure of jacket-type offshore oil platforms [60]. One question was whether or not to require an external design review, given the structure of the risk analysis model, the nature of the current design review process, and the nature of the human errors that can lead to failures (e.g., gross factual errors versus errors of judgment, and their severity level). A computation of the benefits of doing so showed that

²³Note that the realizations of these random variables can be represented in a simple way as “low, medium or high,” or by more sophisticated measures involving for example, the individual experience level of the captain and the crew, and the time they have worked together.

²⁴To link the decisions to the response of the operators, one can use a variety of behavioral models, or an economic model such as a “principal-agent” model [59].

Figure 14. Influence diagram showing the structure of the SAM model (system, action, management) for the case of ship grounding presented in Fig. 12.

their costs were inferior to those of adding steel to the structure to achieve the same risk reduction benefits.

Another form of the SAM model was used in conjunction with the risk analysis model described earlier in Fig. 13 to link potential failures of the space shuttle heat shield to decisions and actions of the technicians during tile maintenance. These actions were linked in turn, to management decisions such as time pressures, the space center structure (thus the flow of information), and the incentives to remain with one's job which is provided by NASA's compensation structure [18]. The study showed, for example, the benefits of improving the inspection process by focusing first on the most risk-critical tiles.

Another form of such models designed to link technical failures and human factors is to start with the work process (instead of the system). For instance, the work process analysis model (WPAM) is based directly on a detailed study of the work process and links its elements to the performance of the system's components [61]. Similarly, Galan *et al.* [62] use Bayesian networks to

incorporate organizational factors in PRAs for nuclear power plants.

Extensions to Human Groups, Game Theory, and Counterterrorism

The structure of technical PRA models can also be useful to address problems that require system's analysis and quantification of uncertainties when the system's elements are human groups such as terrorist organizations. The methods can then be used in a game analysis setting, with explicit representation of the adversary's objectives, information, and means [23]—all factors that may not be fully known to the main player.

In one study, systems analysis, probability, and bounded-rationality concepts were used to rank the risks of different scenarios of terrorist attack on the United States [63]. In another application, the simulation of a game between a government and a group of insurgents permitted an assessment of various government strategies [24,64]. The application in that case was an insurrection in the Philippines. It required another way

to represent the failure risk attached to a specified policy as the probability that after a specified number of time periods, the political and economic stability of the country remained below a given threshold. That model allowed assessing various approaches to balancing immediate resource spending to avoid attacks, and long-term expenditures to address the fundamental problems that fuel the insurrection in the first place. In both cases—counterterrorism and counterinsurrection models—the problem was represented by influence diagrams showing the decision process for the two sides involved, and linked by the results of their alternate moves.

The structure of these models and the probabilistic analysis involved are similar to those used to assess the performance of technical systems: identification of the key state variables, of their realizations and distributions, of the failure scenarios, and of the probability distribution of the spectrum of possible outcomes, positive or negative.

Obviously, the PRA methods have limitations [65]. For instance, one can never be sure that all possible failure scenarios have been considered. Indeed, some are difficult to imagine; that is a problem of implementation, specific to each case. More fundamentally, explicit representation of uncertainty is not part of the engineering tradition—and to a large extent, engineering education—in which a deterministic description of risks combined with safety factors is often preferred to probability.²⁵ The problem of course, is that safety factors can be costly, economically inefficient, and inadequate if one does not consider the chances that even with such factors, extreme loads can be greater than the capacities provided, given the safety margins. Another argument that is sometimes advanced is that a risk analysis cannot be done in the absence of sufficient statistical data. In reality, one often performs a PRA of the type described above precisely because there is not sufficient statistical information

at the system level. In that case, a system analysis combined with probability allows addressing problems such as rare events or events that have not yet been experienced. It is true in engineering and in medicine, where new medical devices must be tested in patients in order to gather the required statistics [19]. It is also true in finance where the chances of “perfect storms” cannot be computed directly from the performances of the last decades because circumstances have changed. In many of these cases, the probabilities used in the analysis have to come from expert opinions. These represent the best available information, even though they may reflect some biases that have been described in the literature [67].

CONCLUSION

PRA methods have been developed mostly in engineering and in particular, in the nuclear power industry, to compute the risks of failure of systems for which sufficient statistical data sets do not exist at the system level. They permit prioritization of risk management measures and allocation of scarce risk management resources. They also allow checking of whether the final risk is tolerable. The methods can be extended to involve human and organizational factors and to represent other types of systems including those in which human groups play a role. The main challenge of these methods is in the problem formulation and in the gathering of data. The approaches presented here allow addressing both to the best of the analyst’s ability. The most important feature of these PRA models is that they explicitly represent uncertainties in a systematic way and can support rational decisions, both in government and industry.

AN INTRODUCTION TO R&D PORTFOLIO DECISION ANALYSIS

KELLY J. DUNCAN

Research, Virginia Commonwealth
University, Richmond, Virginia

A portfolio is a purposeful combination of items. For research and development (R&D) portfolios, these items are technologies, projects, or products. Companies have widely varying practices for portfolio selection. This article examines existing literature to determine the key characteristics of a good portfolio and how decision analysis is used to find one. The approach needs to handle multiple objectives, account for project interactions, and address the social aspect of decision making. The resulting portfolio should be aligned with business strategy, balanced, and maximize value. The article introduces general concepts that have been used to select portfolios and reviews specific applications.

HOW DO COMPANIES DECIDE ON R&D PORTFOLIOS?

A survey of 205 businesses shows that the techniques for portfolio management are inconsistent even within industries or groups of successful companies [1]. The survey asked company executives to identify all methods they used as part of their portfolio management strategy. The executives then identified the dominant strategy among the ones they used. Financial methods ranked as the most popular primary technique. These methods frequently include net present value (NPV) analysis for selecting projects. Project selection based on business strategy was also popular. This method allocates a percentage of the available budget to different strategies or divisions. Projects are then added into

the pipeline in these areas until all funding is allocated. Scoring models were next in popularity and establish weights and metrics for various attributes of a project. Scoring methods align expenditures with business strategy but are more cumbersome and less user-friendly than the graphical methods of bubble diagrams and portfolio mapping. The graphical methods are next in popularity. These methods typically plot potential projects on a graph of risk versus reward, although other measures can be used on the axes. The graphical methods are easy to read and tend to produce portfolios that are well-balanced but not necessarily strategically aligned with business objectives. The bubble chart is a popular graphical method [1]. Bubble charts allow executives and decision makers to visualize the entire portfolio from a number of perspectives. The visual representation could look at projects based on the decision maker's preference. Two examples of representations are distribution of projects based either on risk or on launch horizon (near or long term). A simple checklist was the least popular and least effective method identified. In this technique, projects that satisfied a given number of questions made the cut into the portfolio.

When evaluating the characteristics of companies that ranked near the top in R&D, Cooper *et al.* [1] found that the most successful companies relied least on financial methods. The top companies used methods that were understood by the senior management, perceived to be effective, and used in making Go/Kill decisions. The top firms in *Smart Organizations* use metrics to ensure that projects aligned with corporate strategy [2]. They are also able to show what creates value for the company and encourage development of projects that increase the value. Human judgment tops the list of the many techniques for portfolio management reported in a survey of pharmaceutical companies [3]. In the survey, 60% of companies report satisfaction with their current portfolio management strategy. In many of

Figure 1. A decision tree for (a) a simple R&D investment decision (adapted from Matheson and Matheson [2]), and (b) a two-stage R&D investment decision.

these companies, transparency of information for decision making is contributing to their satisfaction. Companies that were dissatisfied based their views on inability to gain consensus and focus on individual projects instead of overall portfolio [3].

Decision analysis is not the most common portfolio selection method. However, it does offer significant advantages over the methods commonly used in practice. In the simplest form, Fig. 1a shows a decision tree for evaluating the value of a given R&D project (adapted from Matheson and Matheson [2]). At an individual project level, the decision is whether to continue investing or to kill the project. If the investment is made, the

decision maker must assess the probability of technical success and then the NPV of revenue generated, if successful. Figure 1b shows a two-stage investment decision with an investment or kill decision and a probability of technical success at each stage. However, each of these simple R&D decisions is made at the project level. The broader question is which set of projects to invest in given a budget constraint. In essence, this becomes a problem of maximizing the value of a set of R&D projects, or an R&D portfolio, given resource constraints. This form of decision was used as early as Balthasar *et al.* [4] and more recently in Sharpe and Keelin [5]. Clearly, a key part of such an

approach is the assessment of probabilities, a topic covered in detail in article titled *Eliciting Subjective Probabilities from Individuals and Reducing Biases* in this encyclopedia.

In this article, we first discuss the complexities of portfolio selection decisions and define five criteria for a good method for making such decisions. We then discuss portfolio selection applications and methods that do use decision analysis and discuss which best meet the five criteria.

THE PROBLEM AND CHALLENGES

The problem of portfolio selection poses a set of unique challenges. Undertaking new projects or products requires accepting some level of risk and addressing the uncertainty of both the technical and market success of the project. Decision makers frequently face the task of balancing benefits against costs and risk of realizing the benefits. Phillips and Bana e Costa [3] identified five challenges specific to the R&D portfolio problem.

1. Benefits are typically characterized by multiple and possibly conflicting objectives.
2. When a large number of alternatives are presented, the decision maker cannot know the details of each well enough to make an informed decision.
3. If resources are allocated to several organizational units based on individual needs, the result is rarely an optimal allocation for the overall organization. This problem is a situation that illustrates the "Commons Dilemma".
4. Many people are generally involved. People providing advice or expert opinions can end up competing against each other. Besides that, it is difficult to identify all the people with the power to interfere with or influence the decision.
5. Implementation by people who do not agree with the resource allocation can lead to small groups of people working on unapproved projects.

Chien and Sainfort [6] described two additional complications associated with portfolio selection. First, decision makers face the challenge of measuring preference for the portfolio as a whole against the preference for specific items in a portfolio. The objectives of a portfolio could include measures such as achieving optimal balance among projects, whereas objectives for an individual project could include different types of measures such as maximizing technical merit. Second, items in the portfolio often have interrelations. According to Phillips and Bana e Costa [3], these problems demonstrate the need for an approach that balances the costs, benefits, and risks and takes into account differing perspectives of the people involved. This objective cannot be accomplished solely with a technical solution. A social process to engage the involved parties is also required. Top performing companies maintain portfolios that are aligned with their strategies and objectives, of high value, and balanced.

This article reviews various decision analysis approaches to addressing some of the areas key to successful portfolio strategy. Applications are evaluated against the following criteria for a good portfolio selection method:

- alignment with strategy
- balance within the portfolio
- interrelationship between items in a portfolio
- maximizing value of the portfolio
- social acceptance (including transparency and gaining consensus), and
- handling of multiple and conflicting objectives.

SELECTING A PORTFOLIO USING DECISION TREES

Jackson *et al.* [7] designed a portfolio of remediation measure at nuclear waste storage sites. The problem consists of a complex set of sequential decisions involving interdependent technologies and uncertainties in cost and time. Over a 75-year period, the Department of Energy (DOE) plans to

remediate landfills throughout the United States and Puerto Rico at significant expense. There are seven technology process steps associated with stabilizing a landfill: (i) characterization and assessment, (ii) stabilization, (iii) retrieval, (iv) treatment, (v) containment, (vi) disposal, and (vii) monitoring. Several technology options exist to address each of these processes. Technologies under consideration range from proven technologies to prototypes still under laboratory investigation. Risk comes from the maturity of a given technology, the ability to characterize and assess a waste site with accuracy, and applying the correct technologies to a given site. To incorporate risk into the tool described, one must clearly define the risk. Jackson *et al.* [7] described the development of a formal decision analysis tool to support the decision maker when selecting remediation technologies. Known life cycle cost (LCC) simulation models within the DOE provide inputs to the tool. Decision analysis techniques combine output from LCC tools with information about technology risk and uncertainty in cost and time.

A senior DOE official defined the appropriate criteria for this model using value-focused thinking. As a result, the decisions focus on risks for cost, time, and safety. The uncertainty and trade-offs between cost and time make utility functions a good fit for this application. The decision analysis tool proposed by the authors uses sequential remediation decisions to determine the total time required for a project. A distribution of the present value of the portfolio cost is produced. Constraints are added to ensure compatibility of projects and adherence to timelines and budgetary requirements. An additive utility function describes the decision maker's preference and utility for time and cost.

Jackson *et al.* created an influence diagram for each process where a technology selection is required. The uncertain events in this model are R&D costs, operations and maintenance (O&M) costs, R&D time, and O&M time. Parameters for the probability distributions in the uncertainty nodes come from estimation of distribution parameters from the LCC model. A selected technology

has a chance of failure that would lead to additional time and costs. The probability of failure of a project contributes additional penalty time and cost to the expected values for a technology. The decision makers use the diagrams to visualize and validate the process. A complete model of the decision combines the seven processes described by the influence diagrams into a decision tree. A partial decision tree is shown in Fig. 2. The decision tree shows the sequential nature of the remediation process. In addition to choosing whether to stabilize and whether to treat or contain, the decision maker selects from several available technologies for each process step.

The model accounts for the attributes of cost and time and the category of each technology. Categories ensure technologies in a portfolio are compatible. These constraints can model several types of technology relationships based on Boolean logic and are similar to the approach employed in multicriteria programming approaches. The total cost and time values constrain the model. A user can use a constraint to penalize any portfolio that exceeds allowed time or budget by assigning. Assessing a high penalty could completely exclude an undesirable portfolio from consideration. Since time and cost uncertainties exist within a portfolio, a portfolio could have a nonzero probability of exceeding either time or budget constraints. The user can penalize a portfolio more as the probability of the portfolio exceeding the limits increases. For example, in a portfolio with a 0.10 chance of exceeding the limits, the user could assign a utility of -0.5 to the leaves of the decision tree that exceed a constraint. The expected utility function would then account for the possibility of exceeding the limits. The decision tree model produces time and expected NPV for cost for each leaf on the decision tree. A utility function for these attributes takes into account the decision maker's preferences as a basis for selecting technologies. Jackson *et al.* developed a general utility function based on information from the DOE. The DOE has a high utility for costs and time that are below the target plus a 10% error and a very low utility for costs and time that exceed the target values. Using lotteries, decision makers

Figure 2. A partial decision tree of the landfill remediation decision (adapted from Jackson *et al.* [7]).

determined the midpoint utilities. From the known points, two exponential utility curves were created. One curve for cost and time is less than 10% above target and the other for cost and another for cost and time that exceeds the target by more than 10%. The user can incorporate the known utility function into the model and choose a portfolio based on highest utility. In this example, the decision makers examined best and worst case values from the portfolio options and a target option. These values determined the starting point for a utility function. The decision maker then adjusted the shape of the function until content with the shape.

Jackson *et al.* used lotteries to establish utility independence for cost and time attributes. To confirm the stronger additive independence condition, the authors presented each of the decision makers a choice between lottery X, which compares low cost, long time with high cost, short time, and

lottery Y, which compares low cost, short time with high cost, long time. All decision makers were indifferent as long as the cost and time were within the established limits. Cost and time satisfy the additive independence constraints if their values are less than the maximum allowed by constraints. If the additive independence conditions are true for both attributes, an additive utility function can represent the decision maker's objective function. The additive utility function is relatively straightforward and relies on a weighting parameter to represent the decision maker's preference between the attributes. Jackson *et al.* are able to calculate multiattribute utility for a portfolio once all weights are assigned and select the appropriate technology for each stage of the process.

Having drawn from multiple methods from the toolbox of project selection techniques, Jackson *et al.* successfully address

the issues of uncertainty as they relate to timing and cost concerns using decision trees and multiattribute utility theory. They also lay out a transparent method for project selection due to the government funding of the process. They address issues of compatibility and balance within this portfolio by requiring the selection of one technology per stage. The approach works well for the specific application but does not address dependence among projects or balance in a portfolio in an application where such specific constraints did not exist.

SELECTING A PORTFOLIO USING MULTIATTRIBUTE UTILITY THEORY

Golabi *et al.* [8] take a portfolio view of selecting solar energy projects and expand on popular techniques for use in government procurement. They address several areas where they identify shortcomings in earlier R&D project selection procedures including: treatment of multiple criteria, handling of project interactions, approach toward nonmonetary aspects of the problem, and the perception of difficulty understanding models. The project they tackle focuses on the selection of solar energy projects for funding. Since the projects focus on increasing the knowledge in this area of study, minimal risk or uncertainty exists. All projects funded will increase the knowledge base.

Golabi *et al.* utilize multiattribute utility theory in order to address the issues identified. For this application, they determine that there are limited interactions between proposed projects. Redundancy in project selection was not required, but diversity in technologies was. In order to use a simple multilinear utility function, the selection of a project must be based on utility independent of its complement. Golabi *et al.* express a concern preference for a project of medium quality versus one with equal chances of high quality or low quality. This preference could depend on the overall quality of projects already included in the portfolio. Since the condition of utility independence is not met, Golabi *et al.* decided to decouple the evaluation of technical merit from the portfolio

problem to avoid the complexity of addressing dependence. The technical evaluators determined that budget and diversity concerns were the primary consideration for the portfolio. Upon reviewing a list of cost and diversity issues, the technical evaluators determined that a portfolio would need to achieve a minimum level of diversity. Below the minimum level, the portfolio would be unacceptable. However, no additional value was gained by increasing diversity beyond this level. Thus, a trade-off could not be made between budget and diversity. Constraints were added to assure that the desired level of diversity was achieved. One example was determining the allocation of funding to small, medium, and large sized projects. In many cases, it was difficult for the technical evaluators to identify the best level of diversity. The portfolio selection algorithm was first run with only a budgetary constraint. The technical evaluators then reviewed the portfolio of maximum technical utility. If they did not think the identified portfolio demonstrated sufficient diversity, then they added diversity constraints and reran the model.

To assess the technical utility of the entire portfolio, the technical evaluators identified 22 attributes of interest (Table 1), the utility function associated with the attribute, and the weights given to each attribute. Projects that did not meet a minimum threshold for technical quality were eliminated from consideration. Computer support was used to calculate the utilities once the technical evaluators had input values for each attribute. Once all the attributes had been evaluated, the model was turned over to a panel to experiment with different levels of funding and diversity and make final project selections. Golabi *et al.* report that this procedure allowed 77 projects to be evaluated over a period of two weeks and the selection of 17 projects to be completed in three days. They report a successful implementation of their procedure to this application.

While being successful in this application, the procedure does not provide a method for addressing interactions between projects that would occur in an industrial R&D setting. It also fails to address risk and uncertainty as the issue was not deemed relevant

Table 1. Technical Worth Attributes for the Solar Energy Project Portfolio (adapted from Golabi *et al.* [8])

1. Concept design and system analysis
a. Application identification
• X_1 = Load characterization
• X_2 = Matchup of array output load
b. System conceptual design
• X_3 = System conceptual design description
c. Analysis, optimization, and trade-off studies
• X_4 = Consideration of system design options
• X_5 = Parameter identification and optimization approach
2. Technical performance and integration
a. Component specification plan
• X_6 = Specification of array
• X_7 = Specification of other major components
b. System control of interfacing
• X_8 = Understanding of system control and operation
• X_9 = Interface with other energy sources
c. Evaluation of potential performance
• X_{10} = Evaluation of potential performance
d. Development of major components
• X_{11} = Development of major components
3. Implementation plan
• X_{12} = Definition of work tasks for phase 1
• X_{13} = Identification of team members for phase 1
• X_{14} = General phase 2 and 3 plans
• X_{15} = Program management for phase 1
4. Proposer's capabilities
• X_{16} = Experience of firm(s)
• X_{17} = Experience of personnel assigned to project
• X_{18} = Disciplines of personnel
5. Other characteristics
• X_{19} = Accessibility to technical community and visibility to public
• X_{20} = Potential for low cost
• X_{21} = Percent of load met by photovoltaic system
• X_{22} = Institutional considerations

to the specific decision process described. Golabi *et al.* do describe a more rigorous check of the conditions required for a linear-additive utility function than commonly considered.

DEVELOPING PORTFOLIOS USING STRATEGIC THEMES

Poland [9] and Skaf [10] described the evaluation of portfolios for a variety of industries including pharmaceutical, plastic and packaging, oil and gas, and entertainment. Both authors draw on their experience in consulting with Strategic Decisions Group. Poland focuses on addressing the uncertainty inherent in portfolio problems. He also proposes a unique approach for grouping a portfolio that aligns with the business strategy. The approach Poland describes for setting of portfolio themes is also utilized in Skaf's application in an upstream oil and gas organization.

The assessment of uncertainty by calculating probability distributions on key value measures such as NPV is computationally complex. Poland proposes a simplified method for assessment of the portfolio distribution. The method attempts to balance the communication challenge of presenting a large number of probability distributions for multiple businesses in a meaningful way. A presentation with too little detail could mask important insights. A presentation with too much detail could lead to undue focus on certain details and detract from the high level approach to the analysis [9]. The computational requirements for this type of work are high. For example, describing portfolios for a plastics and packaging company with 20 businesses would produce a probability tree with approximately 3.5 billion branches. Poland limits the expansion by focusing on uncertainties with the most impact on the outcome as determined by a tornado chart and fixing the value at the mean for all low-impact items. In many long-term business models, the top five uncertainties can often account for nearly 90% of the total variance, but in portfolio evaluations, many more uncertainties could be required.

Poland [9] uses decision trees to calculate the distributions for various strategies for each business, analytically combining the moments of the distributions for a given portfolio, and fitting a distribution for overall risk and return. Initially, the consultants evaluate the distributions of business value for various business strategies. Then the senior management sets an overall portfolio strategy theme that would guide the strategy for each business. The theme allows management to account for constraints not explicitly modeled and to some extent could address interactions between items within the portfolio. For example, an overall “Aggressive” strategy could lead to an “Expansion” strategy for Business 1 and an “Acquisition” strategy for Business 2.

The portfolio strategy drives the business-level strategy and thereby portfolio value. Both global uncertainties and business-level uncertainties affect portfolio value. The consultants needed to determine how to approximate distributions of portfolio value quickly, given the distribution of value for each value measure, strategy, business, and global scenario. The solution has four steps: summarize business value distribution with the first three cumulants (mean, variance, and skewness); sum cumulants across businesses to get portfolio values (based on the assumption that the values from each business are independent for a global scenario); convert the portfolio cumulants for each global scenario to raw moments and find the overall raw moments for the portfolio; and, fit a smooth distribution to the moments.

In a workshop setting, the consultants used a spreadsheet implementation allowing for quick and interactive use and summarizing the results in a user-friendly flying-bar chart. During the workshops, many strategy themes are explored to account for constraints such as resources not accounted for with this value model. The consultants have used these techniques in the areas of drug development, oil and gas fields, telecommunications, agricultural products, and potential TV pilot shows. If some subsets are highly correlated (such as two drugs that could cannibalize each other’s markets), they are

preevaluated as a single combined asset. Other scenarios could also lead to evaluation of subset groupings. Another challenge occurs when the probability distribution is not accurately represented by the first three cumulants [9].

While the strategy method does take into account alignment, a key item in successful portfolios, it neglects to address how one would evaluate an individual business-level strategy. For example, there is no explanation for how to choose which “Expansion” plan to apply to Business 1 in the “aggressive” portfolio strategy. Poland’s strategy also mentions the issue of interaction in the form of cannibalization but ignores how one evaluates interrelated products as a single asset.

A HIERARCHICAL DECISION PROCESS

Peerenboom *et al.* [11] takes a hierarchical approach in allocating funds to a supplemental environmental program (SEP) based on synthetic fuels. The funding was tied to a multibillion-dollar loan agreement between the DOE and the Great Plains coal gasification facility. The funding requirements for the proposed projects exceeded the available funds by more than a factor of two. Also, national attention was focused on the Great Plains facility [11]. Thus, DOE chose decision analysis to produce a well-documented and traceable record of the decision process.

The DOE established a steering committee and five technical subcommittees to develop the SEP. Each subcommittee proposed a number of detailed studies for health or environmental concerns. The subcommittees did not have individual budget constraints, but the overall budget was \$12 million. The budget allocation decision was complex: the organizational structure included five independent subcommittees; there were uncertainties around research needs, data availability, and costs; value trade-offs were required at both the committee and subcommittee levels; there were numerous strategies of more than 100 projects to evaluate.

The procedure used builds on previous applications of decision analysis techniques to rank projects and evaluate portfolios. It

uses a hierarchical structure to integrate lower level and portfolio level decision analysis. The procedure was tailored to the structure of the committee and subcommittees. Each subcommittee was responsible for ranking its proposed studies. The subcommittee then quantified the degree to which a portfolio met a set of portfolio objectives as a function of funding level. The subcommittees used this information to produce a standardized set of performance curves [11].

The analysts followed a four-step procedure. Step 1 defined the portfolio objectives and attributes. Committee members developed a hierarchy of objectives. Specific objectives were used to build up to broader, more general objectives. The committee then developed scales and attributes for each objective to indicate how well each portfolio objective was met by subcommittee plans. Step 2 ranked the subcommittee studies and developed performance curves. Each subcommittee developed objectives that were more specific than the overall portfolio objectives. This step required quantifying a multiattribute utility function that represented the subcommittee chairperson's preferences over the subprogram objectives. The process involved determining: (i) the trade-offs the chairperson was willing to make between competing subprogram objectives, and (ii) the chairperson's attitude toward risk. The subcommittee evaluated each proposed study in terms of the utility function developed previously, used probability distributions to represent uncertainty, ranked studies on the basis of expected utility, and performed sensitivity analysis. This step links lower and higher levels in the hierarchy. Each subcommittee quantified how well its proposed studies met the portfolio objectives for given levels of funding. As funding levels were reduced, lower ranked studies were cut first in most cases. Subcommittees reviewed the proposed plan to assure that the selections made sense together. Step 3 quantified preferences for portfolio objectives defined in Step 1. In this step, the committee quantified a multiattribute utility function to represent the committee chairperson's preferences over portfolio objectives. In addition to determining chairperson's value trade-offs and attitude

toward risk, the committee addressed utility trade-offs between the five subcommittee plans. This evaluation produced a set of subprogram scaling constants. Step 4 evaluated and compared feasible funding strategies to finalize SEP portfolio. A model using a backward dynamic programming algorithm to maximize utility from the funding of studies in the subprogram areas was used to identify and evaluate the large number of feasible funding strategies. The hierarchical approach came in at Step 2 when the subcommittee sets priorities for its set of subprogram studies. This feature is a major contribution to this procedure but represents only one input into the portfolio level decision making.

At the portfolio level the chairperson identified comprehensiveness, relevance, and cost effectiveness as the broad areas of concern. The committee established objectives, attributes, and scoring criteria for each area of broad concern. Performance curves were created for each attribute to show how well the subcommittee portfolio would do based on a given percentage of requested funding. The performance curves show that for the attribute of coverage, the value is 100% at full funding of the toxicology subprogram. If funding drops by 20%, the coverage of the toxicology subprogram decreases by nearly 50%. The performance curves allow the portfolio to be assessed as a whole unit.

The steering committee allocated a reduced amount of funding of \$9 million across the five subcommittees. Prior to final allocation sensitivity analysis was completed on changes in levels of (i) subprogram scaling constants, (ii) portfolio level utility function scaling constants, and (iii) subprogram performance curves. The chairperson adjusted the funding priorities from the model following extensive reviews and discussions with stakeholders. This adjustment impacted only three of the 88 proposed studies [11].

The method described by Perrenboom *et al.* addresses alignment with strategy and handling of multiple criteria. It also creates a transparent process for the decision and allows for adjustment to build consensus among committee members. Some of the attributes, such as coverage, defined at the

portfolio level address the balance in the portfolio. One consideration not explicitly modeled was interactions between funded projects.

DECISION CONFERENCING TO DEVELOP PORTFOLIOS

Phillips and Bana e Costa [3] describe a multicriteria decision analysis approach to portfolios that they have utilized in numerous consulting applications in various industries. They use multiattribute utility theory, but place a greater emphasis on the social aspects of the decision than, for instance, Golabi *et al.* [8]. Much of their focus is on transparency and consensus building. The primary metric used in their evaluation of projects is value for money determined by the ratio of risk-adjusted benefit to cost. They noted that, much literature recommends this approach. However, in practice, most companies without formal decision analysis support rely on just the expected benefit. Figure 3 shows that picking elements of the portfolio with the highest expected benefit is not the optimal use of the budget. The benefit only curve is always under the cost adjusted benefit curve.

Similar to the approach previously described by Golabi *et al.*, Phillips and Bana

e Costa collapse multiple dimensions of benefit into a single risk-adjusted benefit. The benefit criteria must be mutually preference independent in order to use an additive value function, where the overall value of option i is described by the equation below

$$V_i = \sum_j w_j v_{i,j},$$

where, $v_{i,j}$ represents the value associated with consequence i on criterion j and w_j represents the weight assigned to criterion j .

Several software programs exist for portfolio analysis. Phillips and Bana e Costa describe the approach taken in the software package EQUITY. The basic structure mimics an organization of K areas whose options are appraised against J benefit and risk criteria, producing $K \times J$ scales. The options for each area are appraised against each criterion separately, resulting in a value score $v_{i,j}$ for each option i on criterion j , such that for each scale 100 represents the most preferred option and 0 the least. Then each of the scales for criterion j will be assigned a within-criterion weight, w_j , using swing weighting. The scale associated with the largest difference in value between two reference points is assigned a weight of 100, and others are given a weight relative to 100. The scales assigned within-criterion weights of 100 for each criterion are compared for their swings, producing a set of across-criteria weights w_j . Value scores, within-criterion weights, and across criterion weights are required inputs for EQUITY to calculate the overall value. EQUITY then calculates the benefit-to-cost ratios by dividing each option's overall value by its total cost.

This process results in a single value-for-money triangle associated with each option. The triangles are stacked in declining order of value-for-money priority to create an efficient frontier of projects as seen in Fig. 4. The portfolios of projects up to a given budget are examined and projects that fall outside of the portfolio are examined to make sure exclusion is realistic. The shaded area under the efficient frontier includes all possible portfolios.

At this stage in the decision process constraints are introduced. The decision maker

Figure 3. Portfolio value with increasing budget when chosen in order of highest benefit/cost ratio versus just highest benefit (adapted from Philips and Bana e Costa [3]).

Figure 4. Illustration of the efficient frontier (adapted from Phillips and Bana e Costa [3]).

can determine that an excluded project is too far along to stop or that new projects are infeasible due to other current conditions. The decision maker can propose a portfolio of current projects only. This proposed portfolio, P, is below the efficient frontier. Figure 4 shows that an improvement could be made by moving to portfolio C (same benefit lower at a lower cost) or portfolio B (same cost increased benefit). In 20 applications of Equity, benefit of moving from P to B averaged 30%. This approach helps decision makers make difficult decisions to close down projects that do not look promising. Participants also gain an understanding that what is best for an individual area is not always best for the whole organization.

Portfolio item dependencies are handled visually, following an ad hoc procedure. If the proposed portfolio includes or excludes two dependent projects, no further action is required. Otherwise, the omitted project is manually included and the resulting portfolio analyzed. If two projects are truly dependent on each other, it may be more effective to model them as a single option. Phillips and Bana e Costa pointed out that it is most efficient in practice to focus only on a few important dependencies. A major challenge facing consultants is managing the trade-off between sophisticated modeling and social acceptance of the process. In opting for an approach that favors social acceptance,

Phillips and Bana e Costa must necessarily simplify the complex issue of project dependence. Alignment to objectives is considered in the benefit assessment. The model itself does not account for a balance in selected projects but balance is considered in the decision conference by visually imposing additional constraints as requested to explore balance across various dimensions. Phillips and Bana e Costa place the most emphasis on transparency and acceptance of any of the studies surveyed in this article.

A CONTINGENT PORTFOLIO PROGRAMMING APPROACH

Gustafsson and Salo [12] point out the limited acceptance of the decision analytic method in industrial portfolio selection. They suggest that the slow industrial uptake is due in part to the inability of existing methods to address all areas relevant to the problem. They build on the existing work from decision analysis, R&D management, and financial portfolios to develop the contingent portfolio programming (CPP) method. In addition to drawing on multiattribute methods, Gustafsson and Salo identify optimization models and dynamic programming models as the most relevant to the portfolio problem. Optimization models can capture project interactions and resource constraints, but traditionally fail to address uncertainty. Gustafsson and Salo consider decision trees and real options analysis to be in the category of dynamic programming. This type of modeling captures the sequential nature of decision making, but fails to address project interactions or resource constraints. They point to the options literature that addresses risk preferences but fails to mimic a continuous range of options not a discrete set such as in project selection. Smith and Nau [13] and Perdue *et al.* [14] also integrate decision trees and real options.

CPP provides a methodology for a decision maker to select risky projects over multiple time periods. The CPP approach incorporates decision trees to mimic flexibility of the decision maker to make ongoing go/kill decisions based on available information. CPP

Figure 5. Decision trees for two projects with common state uncertainties (adapted from Gustafsson and Salo [12]).

offers flexibility to accommodate a range of risk attitudes. The CPP model is defined by resource types, a state tree, and decision trees by project. The method accommodates many types of resources both tangible (e.g., capital or equipment) and intangible (e.g., skill sets). Future states of nature are represented by a state tree. A decision maker has choices at a number of decision points for each project. At each decision-point, the decision maker

chooses the action taken. Decision variables are defined for each action. The variable is binary with a value of 1 if the action is made and 0 otherwise. Sample decision trees are defined for two projects A and B and shown in Fig. 5. The same states from the state tree are included in each decision tree, allowing for project dependencies.

Resource flows are defined at each state. Resources can either be gained or consumed

at each point depending on actions chosen by the decision maker. In evaluating this decision, the decision maker's objective is to maximize the utility of the initial position. Gustafsson and Salo focus on a special case that has a reasonable model of risk aversion and is appropriate for linear programming (LP). In addition to the objective function, they define several classes of constraints including decision consistency constraints, resource constraints, and a number of optional constraints. The simple two-project example demonstrates the benefits to considering the projects together instead of each individually. Project A and B succeed inversely. Project A fares better if state S_1 occurs in period two and Project B fares better if state S_2 occurs. Either project selected individually would have a negative NPV. If the decision maker invests in both projects in the first stage and then makes a decision about which project to fund for the second phase depending on the current state of nature, the expected NPV is positive. The diversification of the portfolio mitigates some of the risk. As the number of projects, resources, and constraints increase the problem becomes more computationally complex. Gustafsson and Salo test a number of scenarios using C++ and an LP solver. They find that LP models can be solved in a reasonable period, but the time to solve mixed integer programming (MIP) formulation increased exponentially with the number of integer variables.

Gustafsson and Salo recommend theoretical extension of the model to include more complex resource dynamics. They identify situations where decision trees can be defined for each project and correlated projects. The more complex theoretical approach that Gustafsson and Salo embrace stands in stark contrast to the beliefs of Phillips and Bana e Costa [3] that lean to a simplified model and rely on social process to guide decision making.

CONCLUSIONS

The topic of R&D portfolios is complicated and demands adequate tools to address all relevant concerns. Each method described herein has its own advantages suited to

the specifics of each application. However, Phillips and Bana e Costa [3] and Gustafsson and Salo [12] performed well, generally on our five criteria of a good portfolio selection method. The former approach ensures alignment with strategy, balance across the portfolio, value maximization, consideration of conflicting objectives, and an exemplary social process. Interrelationships within the portfolio are handled in an ad hoc manner. The latter approach is more technical with less social emphasis, but also offers alignment with strategy, balance across the portfolio, value maximization, consideration of conflicting objectives, and explicitly models portfolio interrelationships with the state space diagrams.

Thus, the question turns to the level of detail needed in a model or technical solution versus the social process, traceability, and simplicity of the approach. The industry in question and the corporate environment must affect the choice of tool for a specific application. Keeney and von Winterfeld [15] discuss "practical" value models, noting that it is not always necessary or desirable to construct a complex value model even though it might be theoretically justifiable. They also acknowledge that in some cases theoretically valid assessment procedures are not required. The appropriate level of complexity is driven by the decision scenario, the resources available to gather data or implement a model, and the time allowed for making the decision. Phillips [16] discusses a similar concept of requisite modeling. A requisite model is one that is sufficient to resolve the issues under consideration. The iterative process between consultants and decision makers to define the model increases the understanding of the situation and resolves decision makers' concerns on validity of output from a model. A model is then requisite when no additional insight is evolving. In the end, the specific application for portfolios and the industry in question will drive method selection and the implementation plan.

"If education is always to be conceived along the same antiquated lines of mere transmission of knowledge, there is little to be hoped from it in the bettering of man's future."

— Maria Montessori

INTRODUCTION

A number of studies have found that undergraduates may not be learning what instructors would hope in undergraduate mathematics courses. Traditionally, instructors of mathematics have rationalized the process of students turning away from mathematics as a process of weeding out students unfit to study mathematics. However, evidence from "Talking About Leaving" [1] casts doubt on this perspective. This study found that students who switched out of mathematics and other sciences were not necessarily failing out of courses; on the basis of grades, even grades in the major, it was difficult to predict who would switch and who would remain. Instead, the primary reasons for switching were based on the way the courses were taught. Indeed, the top four factors reported as contributing to students' decision for switching majors are:

1. lack of/loss of interest in science, mathematics, and engineering (SME),
2. non-SME major offers better education/more interest,

3. poor teaching by SME faculty,
4. overwhelming curriculum overload and fast pace.

Rather than the common notion that students leave because they cannot perform in the discipline, these reasons, although more broad than teaching alone, highlight that the way courses are commonly taught is a primary problem.

In addition to the problem of capable students leaving mathematics for other disciplines, there is the issue of the skills and beliefs of students who complete courses in mathematics. Muis, in her review of the literature [2], found that across 33 studies of students from first grade through college mathematics, there is a pervasive belief that only geniuses are capable of understanding or doing mathematics, that good students can solve mathematics problems in 5 min or less, and that one succeeds in mathematics by following procedures described by the instructor to the letter. Muis terms these nonavailing beliefs as an indication that such beliefs are correlated with poorer learning outcomes. These beliefs are held even in a tenth-grade geometry class, as observed by Schoenfeld [3], in which there were high-achieving students, as measured by standardized tests.

Studies also indicate that students are unable to apply what they know. Research by Selden and colleagues [4–6] are illustrative of students' difficulties. In their work, the researchers demonstrated that students with C's, as well as those with A or B grades, had very little success in solving nonroutine problems, even when associated tests showed that the students possessed the requisite algebra and calculus skills. Let us take the study by Carlson [7] as another example. Carlson [7] studied students who had just received A's in college algebra, in second-semester honors calculus, or in first-year graduate mathematics, and, from examinations and interviews, found that not even the top students completely understood the concepts taught in a course, and when faced with an unfamiliar

problem, they had difficulty in utilizing material recently taught.

Another study illustrating the issues faced by collegiate mathematics instructors is work on proof schemes [8]. Harel and Sowder, through data amassed from 128 students in six teaching experiments, described three broad categories of proof schemes, which they defined as consisting of “what constitutes ascertaining and persuading for that person.” Many students exhibited external conviction proof schemes, meaning that what the students found to be sufficient justification depended on things such as an authoritative instructor or an authoritative book, on the appearance of the argument, or on not-necessarily-meaningful manipulations of symbols. Other students exhibited empirical proof schemes, in which evidence from examples is considered sufficient justification. Only the third category, analytical proof schemes, contained those students whose views of proof were consistent with mathematical proof.

In contrast to this evidence, in the remainder of this article, we will describe inquiry-based learning (IBL) as a means to actively engage students in learning mathematics, and we will review evidence suggesting that IBL may improve student outcomes on measures such as problem solving and beliefs about mathematics, while not sacrificing outcomes on basic skills.

IBL encompasses a fairly broad range of approaches to course design and delivery. Historically, many practitioners of IBL in mathematics trace an influence to the mathematician RL Moore. Moore taught mathematics with an approach that we can consider an example of IBL. What is often called the *Moore method* [9] has many variants, and taken as a whole, these are indistinguishable from the approach we call IBL. At its core, IBL is a paradigm in which (i) *students are deeply engaged with mathematical tasks* and (ii) *there are opportunities for substantive collaboration with peers*. These are the foundational principles on which IBL is built.

WHAT DOES RESEARCH INDICATE ABOUT INQUIRY-BASED LEARNING COURSES?

In mathematics, the research base supporting IBL is still developing, but the studies that do exist support IBL as a means to achieve outcomes better than lecture-based courses on measures such as problem solving and beliefs about mathematics, without sacrificing outcomes on procedural knowledge. This finding has held across studies large and small, in calculus and upper division mathematics, and is consistent with the larger research base on IBL.

Smith [18] compared students in two inquiry-oriented number theory courses to students in a number theory course taught via the traditional lecture approach, by interviewing a small number of students from each course. The students from the IBL section exhibited quite different views of proof and approaches to proof when compared with the students from the traditional course section. In particular, students from the IBL sections approached proofs by trying to make sense of the statement and would work through examples to generate insight into the idea of the proofs, while students from the traditional section would search for proof techniques and were reluctant to work on examples, as examples were not going to be part of the proof. Students from the traditional course section tried to relate a current proof task to other proofs, based on the surface features (for instance, “prime” is mentioned, whether or not primality is actually an essential condition for the proof), rather than based on understanding the concept. The IBL students also sought to understand their proofs and try to write them in ways that were meaningful, whereas the traditional section students were more interested in figuring out what they were supposed to do. Although these findings are limited by a small sample, they are suggestive of results that arise from larger projects, which we review next.

We turn our attention to studies of other IBL courses, not necessarily proof-oriented courses. The Inquiry-Oriented Differential Equations Project investigated student learning of a specially designed curriculum

in which the course goals were described as follows:

We wanted students to essentially reinvent many of the key mathematical ideas and methods. . . We wanted challenging tasks, often situated in realistic situations, to serve as the starting point for students' mathematical inquiry. . . We wanted a balanced treatment of analytic, numerical, and graphical approaches, but we wanted these various approaches to emerge more or less simultaneously for learners [19].

Students in the course developed, used, and compared multiple approaches to solving differential equations. This contrasts with the traditional model of the instructor demonstrating solutions to well-defined classes of differential equations and then assigning the students similar problems to practice solving. Courses using this approach were compared with courses using the traditional approach. At the end of the semester, students from the inquiry-oriented courses performed similarly to the students compared on procedural items, but outperformed students from traditional courses on modeling and conceptual tasks. In a follow-up study one year later, students from one of the inquiry-oriented courses and one of the traditional courses took a retention test, again composed of procedural, modeling, and conceptual tasks. In this case, the results were the same: students from the inquiry-oriented course performed similarly to the students from the traditional course on procedural items, but outperformed on modeling and conceptual items. This finding held even though 75% of the traditional students and none of the inquiry-oriented students had taken a course in numerical differential equations in the interim year [20]. This finding, that students in IBL courses tend to perform about as well as students from traditional sections on procedural items, but do better on conceptual items, was confirmed by six of the seven studies that reported statistical significance, as reported in a review of studies of reform calculus [21]. Thus, across eight studies of calculus and differential equations, students from

IBL courses tend to perform better than comparison students on conceptual items, with no cost to performance on procedural items.

Laursen and her colleagues [22] engaged in a multiyear, multisite study of the impact of IBL on students. Mathematics departments at four research universities (three public and one private) agreed to offer IBL courses and to participate in data collection. Across a variety of courses at the four sites, the main features of students solving problems from a carefully sequenced problem set, with class time primarily spent on student-centered activities, and with the instructor participating but not significantly in the role of lecturer, were all present to varying degrees. Overall, 60% of IBL class time was spent on student-centered activity, whereas 87% of comparison non-IBL course time was spent listening to the instructor talk. Surveys asked students to report gains in several areas. Students who took IBL math-track courses (i.e., excluding courses for future elementary teachers) had higher gains in areas such as understanding of concepts, improved thinking and problem-solving skills, gains in confidence and persistence, collaboration, and comfort in teaching mathematical ideas to others. Preservice teachers did not have a comparison group of non-IBL preservice teachers. However, preservice teachers had gains higher than math-track non-IBL courses in areas such as applying mathematical knowledge, collaboration, and comfort in teaching mathematical ideas to others. In addition, students with low prior achievement who took IBL courses and then took math courses after their IBL experience also tended to earn higher math GPAs in comparison to low-achieving students who took non-IBL courses. In other words, students with low prior achievement in mathematics made stronger gains in mathematics achievement by taking IBL courses. These findings add depth to the picture of student performance painted by the earlier studies, by highlighting particular ways in which students perceived their own gains both on content learning and on beliefs and attitudes toward mathematics.

These findings in collegiate mathematics are similar to the findings elsewhere, where there is more evidence investigating various forms of IBL in college classrooms. The evidence from collegiate science courses indicates that on higher level cognitive outcomes such as thinking, problem solving, and laboratory skills, IBL is superior than traditional science instruction [23].

Support for an IBL approach can also be found in the literature on mathematics education at the precollegiate level. While it is beyond the scope of this review to summarize this literature, we review two studies that take a thorough look at the scope of the differences in student experiences under IBL versus a traditional approach. Boaler [24] conducted a three-year study of two high schools in the United Kingdom, one with a traditional approach and one that used an IBL approach, emphasizing projects throughout the curriculum. In spite of a de-emphasis on textbook-like basic skill problems, students at the IBL-oriented Phoenix Park performed similarly to the traditionally taught Amber Hill students. Simultaneously, Phoenix Park students outperformed Amber Hill students on contextualized problems. Moreover, while Phoenix Park students were learning to apply the mathematics they were learning, Amber Hill students exhibited cue-based behavior, and possessed a kind of “inert procedural knowledge” [24, p. 59] that they could only use in a narrow range of textbook-like situations. In a separate four-year study in the United States [25], a comparison of 700 students across three high schools yielded similar results in favor of the school with the inquiry-based approach.

Summarizing, we find that comparative studies indicate that students in IBL courses perform better than students in traditional courses on measures of conceptual understanding, perform about as well on measures of procedural competence, and report higher gains in areas such as confidence and persistence, and the ability to teach or explain mathematics to others.

BASIC COMPONENTS OF INQUIRY-BASED LEARNING

First, we present a typical first couple of days in an IBL class to give a sense for the overall structure of an IBL class, and then later we describe principles and structures typical of IBL. What is presented in this section represents the main features of IBL courses. Individual instructors have developed various adaptations of IBL, and describing the entire portfolio of IBL implementation is beyond the scope of this article. What we strive to do is to convey the main principles of IBL teaching in mathematics, and leave open to the reader how it might vary depending on the course, students, and other factors. Moreover, we describe specifics about IBL from a mathematician’s perspective, and emphasize that the core ideas presented in this article have broad applicability across all fields of study. Indeed, as subjects become more applied in nature, it is perhaps easier to motivate students with relevant problems presented in context.

Typical day one: After a brief introduction, students are given problems from a well-crafted problem sequence. They start working on the problems in class. Basic definitions and a handful of starter problems are given to the students. Starter problems are first and foremost accessible questions that ask students to unpack the meaning of definitions, develop specific skills, or work with fundamental concepts.

Definition 1. An integer N is even if and only if $N = 2k$ for some integer k .

Definition 2. An integer N is odd if and only if $N = 2k + 1$ for some integer k .

Problem 1. Prove or disprove the following statement. The sum of two even numbers is even.

Problem 2. Prove or disprove the following statement. The sum of two odd numbers is odd.

After giving the two definitions and a list of problems (including problems 1 and 2), the instructor asks the students to work on the first few problems on their own. After students have had a chance to develop their

own ideas, they may be asked to share their ideas with one or two partners. Next, the class is instructed to produce, as best they can, a proof of problems 1 and 2. As students are working and completing their proofs, the instructor's role is to visit with several (possibly all) groups, and find two groups capable of presenting proofs to the first two problems. After the class has had enough time on these problems, two individuals or groups are selected to present a proof to the class for problems 1 and 2. The students in the class would be given the role of making sure that the proofs are correct. The instructor's role is to facilitate the discussion of the proofs, specifically managing the question-and-answer component of the discussion. All of this should be carefully explained to students.

During and after a student (or group) presents a proof, the class is allowed to ask questions for clarification, to point out gaps in arguments, and to offer suggestions. Once all questions are fielded, then the class is asked to approve the solution, request clarification from the presenter, or disagree with the solution. If the solution is approved, the presenters receive credit for producing a correct proof. If the class cannot arrive at a consensus, the outstanding issues are typically written on the board as questions for students to work on. A choice is now made by the instructor to continue working on the questions that were raised or to ask the presenter(s) to return the next class period with an updated solution. Then the class moves on to the next problem. Normally, with well-chosen starter problems, the class as a whole makes it through the first few problems without difficulty.

One of the goals of day 1 is to get some students to successfully solve a problem and present a proof in class. This establishes how the class will transpire for the rest of the term. At this point of the course, it is vital for an IBL instructor to very clearly outline (i) students' roles as young mathematicians and problem solvers; (ii) the instructor's role as facilitator, mentor, and coach; and (iii) how students will be stuck and that being stuck is ok, provided these situations are turned into opportunities to search for

new ideas and strategies. Instructors often start the first day by informing the students of the above, and revisiting these topics as necessary throughout the term. When the first period is about to end, students are asked to continue to work on the next five to seven problems from the list. Their standing instructions are to work on problems outside the class and return to the next class with their own solutions. All outside resources are strictly forbidden, and their goal should be to get stuck and enjoy the growth that comes from being stuck. One of the most important messages students should take to heart and instructors should develop is, "Being stuck is okay!" In fact, helping students deal with being stuck is one of the most important skills needed for a successful IBL course and is discussed further under Students' Roles and Some Pitfalls to Avoid.

On day 2, class starts with the instructor reminding students of their roles and how class will proceed. Since only a few students have presented thus far, volunteers are requested among those with a proof of one of the next four to five problems (e.g., problem 3 and on). Students are selected and asked to go to the board and write their proofs simultaneously. When all students are done writing their proofs on the board, the student with a proof for number 3 is asked to present his/her proof to the rest of the class, line by line. The class is asked to check that the presented proof is correct. If errors are found, then the class is obligated to ask questions and offer suggestions. If a presenter is unable to fix a problem at the board, they are given the option of returning the next class period with a fix. Otherwise, if all the steps are fine and the entire class is satisfied with the solution, then the solution is deemed correct, and the next presenter will then share his/her proof of the next problem. The course proceeds in this way.

After a few days, some of the students will have presented, and some will not have had a turn at the board. One way to keep students motivated and provide ample opportunities for all students is to keep track of who has presented, and to pass out a sign-up sheet at the beginning of each class meeting. The sign-up sheet will have the students

listed alphabetically along the left column, and the next 10 or so problems listed across the top. Students can indicate the problems they believe they are capable of presenting by marking appropriate columns with an X. Students who have presented the fewest number of times get first priority. Instructors also have the option of seeking out at the beginning of class those students with the fewest presentations to ask them whether they have a proof to present to the class. Occasionally, it becomes apparent that a student will not present unless asked, in which case the instructor may choose to respond by assigning the student a specific problem ahead of time and asking the student to prepare a proof for presentation. Additionally, working in pairs on accessible tasks in class is another strategy to generate opportunities for reticent students to present in class. (Extremely shy students can sometimes be accommodated through written work in lieu of presentations and/or giving presentations in office hours. It is emphasized that such instances are rare and special, and are handled outside the standard operation of the course.) Therefore, mechanisms exist to provide for students a way to fairly distribute problems and ensure that every student who puts forth a reasonable effort will have chances to present their solutions.

In summary, the basic components of a typical IBL course are:

- a well-crafted problem set,
- the students' role defined to include problem solving and presenting solutions in class,
- class discussion and peer review of all solutions,
- the instructor's role to primarily guide, coach, and mentor.

BIG IDEAS IN IBL TEACHING

In addition to the basic structure of an IBL course, it is valuable to consider some of the "big ideas" in IBL teaching. These ideas are how to construct appropriate course materials, deal with common pitfalls, expand on the

instructor's role, and build a community of learners.

IBL Course Materials

Course materials are generally constructed so that a standard textbook is not used, although there exist books specifically designed for IBL courses. IBL course materials consist of a well-crafted list of problems, theorem statements, axioms (or basic assumptions), and definitions. The list of problems is normally given to students as one section or one unit at a time. An important feature of these IBL course materials is that they do not contain proofs, solutions, or carefully worked examples that students can mimic. Instead of presenting answers to students, students are asked to make sense of the questions and to construct their own solutions. Students must read and understand definitions, construct examples, explore strategies to solve problems, examine other students' proofs, and find their own proofs/solutions to problems that they do not already know how to solve. The nature of the questions tends to be different than standard textbooks, because they must include opportunities for students to learn the big ideas and strategies in the subject. In this way, students are deeply engaged in rich mathematical tasks, and are doing mathematics like mathematicians.

One of the major reasons why problems are handed out one section at a time is that students may decide to take a path that is not the instructor's intended route through the material. The learning experience is akin to exploring a landscape. As students progress through the material, unworked examples and lemmas may need to be added (or subtracted). These alterations tend to be minor, but classes vary from term to term, and there are occasions when students create unexpected paths of discovery. Moreover, such alterations cannot be planned for in advance, because they depend on the specific nature of the mathematics generated by the students in the class. With that said, it is unlikely that major overhauls are required or that the entire course framework comes apart. Additional course material is sometimes needed to help students overcome specific learning

challenges or to honor their ingenuity by finding another path to a solution. Then, the course problem set is a living document.

How does one find IBL course materials? Several problem sets can be found at *The Journal of Inquiry-Based Learning in Mathematics* (www.jiblm.org). This journal is a collection of peer-reviewed and field-tested IBL course materials. In addition to the peer-reviewed materials, the Journal also has links to a separate collection of IBL course materials, which have not been peer-reviewed, but however may be useful to instructors. In addition to the Journal, several IBL textbooks have been published:

- *Chapter Zero* [10],
- *Closer and Closer* [11],
- *Essentials of Mathematics: Introduction to Theory, Proof, and the Professional Culture* [12],
- *The Heart of Mathematics: An Invitation to Effective Thinking* [13],
- *Number Theory Through Inquiry* [14], and
- *Linear Optimization: A Simplex Workbook* [15].

How does one construct IBL course materials (or a module/unit)? In proof-based courses (topology, number theory, algebra, analysis, intro to proofs, etc.), course materials are generally constructed by reverse engineering from goal theorems. The first step is to identify the goal theorems in a course. Goal theorems encapsulate the major learning objectives of the course and from these goal theorems the problem sequences can be reverse engineered via finding all the assumptions, definitions, lemmas, and techniques needed to prove the theorems. These problems are then sequenced and made suitable for one's students. Suitability depends on the level of the course, student body, and the prior student experiences with IBL or problem-solving approaches. One of the advantages of IBL is that course materials can be tailored to specific needs that can vary across institutions and cohorts.

When all is said and done, the problem sequence starts with basic definitions and a

good supply of starter problems to engage students in the topic being studied. The starter problems should be at a level that is easily accessible to all students and leads students toward understanding definitions, core ideas, and fundamentally important techniques. These starter problems lead to lemmas, theorems, and eventually to the first goal theorem. Then the class is on to the next topic or challenge, and students begin again with new definitions, starter problems, lemmas, theorems, and goal theorems.

The following is a list of key components of IBL course materials:

- Units start with first principles and definitions.
- Problem sets include a good supply of “starter problems” so that all students, especially those who struggle the most, have successes early and often.
- The sequence of problems builds up to lemmas and goal theorems.
- The entire course is organized around the goal theorems.

Students' Roles and Some Pitfalls to Avoid

The first and foremost student role is to be a problem solver. Students should do math, be stuck, and think hard about mathematics. This poses great opportunities as well as some pitfalls. The opportunities are clear—students can learn to become better problem solvers and proof writers. Students are to be instructed not to use outside resources of any kind (e.g., web, books, students not enrolled in the class). Instead of looking up answers, their job is to create their own solutions. Although more challenging, it is better for students, as they will develop the capacities that society values, such as problem solving, creative thinking, skillful communication, and experimentation. Despite the benefits, IBL courses often go against students' prior experiences in math classes. Thus, it is very easy for students to fall back on old habits.

Another of the core principles in IBL courses is that students bear the responsibility of evaluating whether a proof or

solution is correct. Answers are deemed correct because the *logic and reasoning* are convincing to everyone in the class. If a student presents a proof to the class, then the students in the class peer-review the proof, just as a journal article is peer-reviewed.

Consequently, the pitfalls are related to the fact that most undergraduates have not had many experiences solving problems on their own and thus they can be uncomfortable and not used to being stuck or confused for relatively long stretches of time. It is vital to understand that in most cases students are *in the process of becoming good problem solvers, but they are not yet fully developed*. Students may utter, “I need to be shown how to solve the problem...” or “I don’t learn this way.” Perhaps students will assume that getting stuck means they do not have the capacity to solve problems. The IBL instructor must first diagnose these issues and then address them quickly to avoid a situation where students shut down and give up. Instructors can

- ensure that there exists a wide range of problems so that all students can successfully solve some problems.
- slow down as needed to provide time for students to work on difficult problems. It is common for IBL instructors to augment a problem set with additional problems that provide more scaffolding of a problem.
- utilize small group work to provide a needed problem-solving activity that can generate new ideas and provide students a chance to ask questions and experiment.
- help students by providing sample strategies that can be employed, for instance reminding students that they should look at examples and try to understand and generalize them.
- coach students through the process of building a sense of proof by making sure students know that being stuck is normal and that help is available to them at all times. It can be helpful to share personal stories or stories from famous mathematicians, for example, Wiles’ work on Fermat’s Last Theorem, to remind students that mathematicians often spend very long periods working to understand a single problem.
- ask students who are frustrated, “How can I help you?” and “What have you tried?” Such prompts guide students to refocus attention on the specific math questions they have. Rather than providing a solution, one could outline some ideas that could be helpful, for example, “Has anyone tried looking at these examples or cases?”

If an instructor does not diagnose and manage student expectations and the natural frustration that arises from the problem-solving process, then this leaves open the possibility that students shut down or give up. Instead, an effective IBL instructor provides the support necessary to keep students engaged in the journey through the mathematical landscape. At the same time, the IBL format provides tremendous opportunities for advanced students to grow, as such students discover their own power to do mathematics, and, with a well-crafted problem set, there are sufficient opportunities for advanced students to solve problems that are at a level that engages and challenges them. Indeed, advanced students should be given problems to match their wit, and in mathematics there exists a vast wealth of problems for such students to tackle.

Community of Learners

An essential feature of an IBL course is the community of learners. The specific arrangement and use of the community differs across instructors. Nevertheless, reliance on some form of collaboration between students is one of the principal features of an IBL course. Some instructors do not allow students to work with one another, except during in-class presentations and discussion. Students are otherwise required to work alone on problems outside class. Others encourage collaboration in and out of class. In either of the cases, a core feature of IBL is the sense that a community of learners is working together to investigate and establish facts, and that the differences are relatively minor in the larger

scheme, in which the main idea is the focus on student-generated mathematics.

SOME DETAILS OF IBL COURSE STRUCTURE

Specific use of examinations, written work, presentations, and other assessments differs by instructors. We present some “canonical forms” that instructors can use as a foundation for their own course. One important concept in choosing a course structure is to provide enough structure for the student body at one’s institution. Some students are more independent, while others are still developing their sense of independence. For courses with students who are less independent as learners, it is recommended that the course be more structured.

- Presentations and final,
- presentations, midterm(s), final,
- presentations, midterm(s), final, homework, and
- presentations, midterm(s), final, homework, and portfolio.

Presentations, midterms, and final exams are generally equally weighted, with a tendency for IBL instructors to put the most weight on presentations. Presentations provide the best opportunities for students to demonstrate their understanding of the material, and should be highly valued as a form of assessment of learning. Note that, depending on the course and the instructor, IBL can be a highly collaborative environment, yet individual accountability is the central feature of a successful IBL classroom, and so individual examinations and/or individual presentations are still used in this setting.

Portfolios can be highly beneficial to learning and can take on several different forms. The main idea behind the portfolio is to ensure that students keep a well-organized, comprehensive set of solutions from the entire term. Portfolios are normally checked two to three times during the term. Other tasks can be included in the portfolio, such as requiring students to select their top eight to ten proofs from the quarter, and/or

a summary essay on the main ideas in the course. The portfolio typically is weighted at about 5–10% of the course grade.

Grading presentations is often a task that new IBL instructors have not done before. Sample rubrics are presented here as models for how to grade presentations and provide feedback.

Sample #1

10	Perfect
8–9	Correct with minor technical issues
7	Incorrect with reasoning why incorrect
0–6	Incorrect

Sample #2

4	I know you understand
3	I think you understand
2	I don’t think you understand
1	I know you don’t understand
0	Nothing turned in

Sample #3 (Translated sample #2 for approximate 90-80-70-60 grading scale)

8	I know you understand
7	I think you understand
6	I don’t think you understand
5	I know you don’t understand
0–4	Nothing turned in

Sample #4

1	Correct
0	Incorrect

Class size affects instruction. Most IBL instructors indicate that small class sizes are ideal, and a class size of about 35 students is roughly the upper limit for a full IBL course. As class size increases beyond 35 students, instructors have fewer options for class activities. In this case, instructors can choose a hybrid IBL structure, which diminishes or eliminates presentations from the grading

system. The designation hybrid IBL is meant to connote a classroom in which students are regularly engaged in sense-making activities, but instructors may still rely on lectures for a significant portion of the class. For instance, one day a week may be reserved for IBL activities. Or, group activities may be interspersed at regular intervals within a lecture. This is a natural consequence of the fact that in large classes, students would present only once or twice a term at the most. Thus, it is recommended that instructors who wish to teach a full IBL course do so in courses with enrollments of 35 or fewer. Hybrid IBL courses can be implemented in larger (and smaller) classes, with the understanding that some of the most effective learning environments are being sacrificed.

WHEN IS IBL APPROPRIATE AND HOW DOES IT DIFFER BY COURSE OR AUDIENCE?

We believe that IBL or hybrid IBL methods are appropriate across the curriculum. The specific methods and course structure are largely dependent on the environmental factors and the students in the course. IBL is most easily implemented in upper division or graduate-level courses that are proof-based. Such courses are self-contained, and students in those courses are more mathematically mature. These courses are generally considered to be the best places to implement IBL, particularly for instructors new to IBL.

In freshmen and sophomore-level courses, student backgrounds, experiences, majors, and intended careers vary more widely. Additionally, students have had fewer mathematics courses and thus need to learn more ideas, skills, and habits of mind compared to an upper division student. In courses such as calculus, instructors may not have the option of choosing textbooks or the topics that must be covered. Further, instructors usually do not have as much leeway or flexibility in time as they would in upper level courses. Thus, a hybrid approach is often employed, where the instructor spends less than half of the time introducing a topic, and students work in smaller groups on problems or well-crafted handouts, based on one section of the textbook.

A particularly important group that can benefit from IBL is preservice elementary and secondary teachers. According to The Principles and Standards for School Mathematics [16] and the upcoming Common Core State Standards [17], teachers will increasingly be asked to teach students critical reasoning and higher-level thinking, such as problem solving. It is very difficult to teach problem solving, exploration, how to handle being stuck, and so on, if one has not experienced them firsthand. Thus, we also advocate using IBL in courses for preservice teachers. The flavor of IBL differs in these courses as the course content is not proof-based and axiomatic for all topics. Nevertheless, problems can still be developed from first principles. Further, students can present their findings and work in groups on tasks that require them to explain or justify why. For instance, most students in such courses have never been asked to consider why “invert and multiply” works, why we do not define division by zero, or why subtracting a negative is equivalent to adding.

CONCLUDING REMARKS

In this article, we have discussed what IBL is, what it looks like in a typical course, general features of an IBL approach, and the research findings that support its use. We end this article with some insights from the field. While the data is compelling, what is equally compelling is how IBL has generated a strong, enthusiastic group of practitioners. The reason lies at the heart of education. It is our belief that instructors are ultimately in the business of transforming lives. Despite the extra work needed to learn how to use and continue to implement IBL, instructors who use IBL see growth in students that goes far beyond just learning more facts. We have witnessed, for many students, a transformation of the students’ relationship with, and approach to, mathematics. It is our hope that readers of this article will be inspired to look beyond mere surface features, and invest the necessary time required to become an effective IBL instructor. Assistance for new IBL instructors is available

at The Academy of Inquiry-Based Learning (www.inquirybasedlearning.org).

Technology, Melbourne, Victoria,
Australia
Tennis Australia, Melbourne, Victoria,
Australia

DENNY MEYER
Tennis Australia, Melbourne, Victoria,
Australia

The modern game of “tennis” began in 1874 as “lawn tennis,” as an outdoor version of the ancient game now known as *royal tennis*. In nearly 100 years, the equipment and the rules hardly changed. Originally designed as a portable game to be played on grassed areas using balls and stringed rackets made of wood, the courts soon became permanent and the surface extended from grass to clay and then, to various hardcourt surfaces. Rackets and balls continued to improve in quality, but remained essentially the same. The three-tiered scoring system of points, games, and sets remained consistent throughout, along with the principle of winning by at least two points (in a game) and at least two games (in a set).

In 1968, the long-standing division between amateurs and professionals ended and tournaments were opened to all players. The game expanded rapidly. The equipment and the scoring system that had served the amateur game for so long were repeatedly thrown into question by technical developments and by the demands of television coverage.

Scientific and technological developments both created problems and opportunities for the game. This article considers some of these developments, highlighting the current and potential use of operations research (OR) and management science (MS) methods in this regard.

CURRENT AND POTENTIAL USE OF OR/MS METHODS IN TENNIS

The following table illustrates how OR/MS methods are currently used in tennis. However, modern technological developments mean that there are now ways to measure many more of the relevant variables, opening up many new uses for these methods. Under a range of topics, Table 1 illustrates various decision problems which can be addressed by OR/MS methods using appropriate objective functions and constraints. These topics are discussed in detail in this article.

DEVELOPING ALTERNATIVE AND OPTIMAL SCORING SYSTEMS

The scoring system used in the modern game of (lawn) tennis is a much simplified version of the ancient game of royal tennis given the absence of the “chase,” the walls, galleries, and other hazards of royal tennis. When Major Walter Wingfield patented the new game (initially called “sphairistike”) in 1874, he patented both the rules and the equipment (a patent which he subsequently allowed to drop). Soon there were many variants to the rules and in the absence of any ruling body, the Marylebone Cricket Club (MCC) was called upon to adjudicate on the rules of tennis. However, the MCC only set guidelines with some variations allowed. The Rules Committee of the first Wimbledon Championships in 1877 adopted a set of rules which then became the standard and have remained fundamentally the same to this day.

Tennis has a unique scoring system, in that it is triple nested (points, games, and sets). One player serves and their opponent receives and the server has two chances to put the ball into play. The same player continues serving until a game is completed, which is won by the player winning the “best of six” points (i.e., first to four points) provided that player leads by at least two points. In the following game, the receiver becomes the server and the players continue to swap roles each

Table 1. Current and Potential Use of OR/MS Methods in Tennis				
Topic	Objective Function	Constraints	Decisions	Appropriate OR/MS Methods
Developing optimal scoring systems	Minimize the mean and variation in length of matches	Integrity of tennis' unique scoring system, better player should win	Alternative procedures and scoring systems	Deterministic optimization using mathematical models
Developing optimal match strategies	Maximize the probability of player success	Surface properties (e.g., court speed), current scoring system	Serving strategy, When to lift	Deterministic optimization, Markov chain and dynamic programming models
Surface optimization	Minimize capital and maintenance costs Maximize income from court hire and the chance of winning	Weather, player preferences in terms of speed and comfort	Choice of surface	Deterministic optimization, Multicriteria optimization
2 Optimizing ball characteristics	Optimize ball speed, spin, trajectory, durability, bounce, etc. Minimize cost effects and maximize ease of play	Surface and racket properties; player ability, style and age; cloth texture	Internal pressure or pressureless dynamic stiffness	Stochastic optimization using mathematical modeling and computer simulation
Optimizing racket characteristics	Maximize ease of play and minimize cost effects Optimize ball trajectory and power for any stroke	Preservation of the nature of tennis, ball, racket and surface properties; racket material, atmospheric conditions	Head size, weight, and grip size; frame stiffness, balance point, sweet spots, swingweight, stability, shock, power, vibration, feel	Stochastic optimization using mathematical modeling and computer simulation
Optimization from a coaching perspective	Optimize performance, minimize injury risk	Physical and mental attributes of player; ball, racket, and surface characteristics	Technical advice and short/long-term training (periodization) plans	Pattern recognition using video footage; deterministic optimization

ω	Optimizing playing technique	Optimize power and control combination	Equipment, surface, athletic, and physical attributes of player, injury risk	Choice of style and technique for individual players	Multicriteria programming
	Minimizing medical risk	Minimize injury risk, doping detection Optimize rehabilitation and training	Player characteristics, opponent's strength; ambient conditions, other risk factors	Tournament rules (e.g., minimum age of players, heat policies, racket design)	Deterministic optimization using mathematical models
	Efficient tournament management	Maximize the number of feasible matches	Availability of courts and players, Maximum time for matches	Match schedule	Constraint programming with heuristic search
	Strengthening the mental side of the game	Minimize variation in playing ability through the control of heart rhythms and emotion	Physical and mental attributes of player; ambient conditions, surface, other risk factors	Choice of techniques for maintaining concentration (e.g., breathing, stalling, grunting, variation in play)	Deterministic optimization using mathematical models
	Accurate player rankings	Maximize accuracy of rankings in terms of performance	Different levels of tennis, singles/doubles, surface, effects of injury	Weightings for importance and closeness of a match, strength of opponent, protective rankings, average or "best of x " results rules	Kalman filter, Monte Carlo simulation, nonlinear optimization
	Improving officiating	Optimized accuracy of line calls and foot faults	Technology used, surface, human error	Choice of method, model, training of officials	Pattern recognition using video footage, deterministic optimization

game. The set is “best of ten” games (i.e., first to six games) provided the player leads by at least two games (called an *advantage set*). A match consists of the “best of three” sets (i.e., first to win two sets) or in Grand Slam men’s tournaments and Davis Cup, the “best of five” sets (i.e., first to win three sets).

The first significant change of the open tennis era intended to help reduce the mean and variation in the length of matches, was to introduce the option of a “tie-break set” instead of an “advantage set.” The tie-break system was introduced by James Van Allen at the Philadelphia Indoor Tournament in 1970 and was the best of nine points. The fact that both players had a match point at four points all, but one player had the advantage of serving soon lead to a second tie-break system, the 12- point method described below. This tie-break system soon became the more popular system and was used at Wimbledon in 1971 (at eight games all, whereas most other tournaments applied it at six all).

The Rules of Tennis [1] published by the International Tennis Federation (ITF) now provide that, if the score reaches six games all, the set can be decided by playing a tie-break game where the first player to win seven points wins the game and the set, provided there is a margin of two points within the tie-break game. If necessary the tie-break game continues until this margin is achieved. Thus, although the duration of a tie-break set is still unbounded, it clearly has a lower mean and variance than the advantage set. The tie-break set is now used in all sets in all tournaments except the Australian Open, Roland Garros, Wimbledon, Davis Cup, and Fed Cup which maintain that the fifth and deciding set (third set for women) should be decided by an advantage set (i.e., requiring a break of service).

Tennis, pushed by the demands of television, searched (and still searches) for a solution to the reasonably unpredictable length of tennis matches, while maintaining the integrity of its unique scoring system. Short matches were accepted, but extremely long matches, primarily brought about by the dominance of the service, became increasingly difficult to handle. Appendix IV, of the Rules of Tennis [1] offers alternative

procedures and scoring methods such as no ad scoring, short sets, match tie-break to replace the deciding final set, and eliminating the let during service. These alternatives have long been used by social players and in selected competitions such as World Team Tennis and Intercollegiate tennis, but were only formally recognized in the ITF Rules of Tennis from 2002. In the forward of Rules of Tennis, the ITF [1] invites interested parties to submit applications to officially trial other scoring systems.

There is a growing collection of computer simulation, probability, and statistical analyses of the official scoring system and alternative more efficient scoring systems. The simplest stochastic models (unipoints) assume all points are independent and identically distributed. A more realistic but more complicated model for elite tennis recognizes there are two types of points depending on which player is serving (bipoints).

Kemeny and Snell [2] modeled a single game of tennis using a Markov chain. Schultz [3] examined the feasibility of using a Markov chain with stationary transition probabilities to evaluate scoring systems. Hsi and Burych [4], taking a bipoints approach, evaluated the probability that a player wins an advantage set. Carter and Crews [5], taking a unipoints approach, found the expected number of points in a game, games in a set and sets in a match. Miles [6], using the bipoints approach, found the expected duration of a set in tennis. Pollard [7] showed mathematically that the expected duration and variance of a tie-break set and match are always smaller than using advantage sets, but the probability that the better player wins is slightly reduced.

Morris [8] introduced the concept of importance for each point played and the more complex notion of “time-importance” where the importance is weighted by the expected number of times the point is played. Miles [9] noted the link between sports scoring systems and symmetric sequential statistical hypothesis testing and examined the efficiencies of sports scoring systems such as tennis. Pollard [10,11] linked Miles’ and Morris’ work and found an important relationship between importance of points within a system and the

efficiency of the system itself. He uses this relationship to find the optimally efficient tennis scoring system. Pollard [12] showed how, in many cases, the relative efficiency of two different scoring systems could be found without calculating the efficiency of each system separately. Pollard and Noble [13] suggested the 50–40 game and showed that it leads to good scoring systems in terms of variance and efficiency, particularly for doubles. Pollard and Pollard [14] generalized the Miles formula from singles (two parameters) to doubles (four parameters) and identified very efficient doubles scoring systems. They also found the moment-generating function for the present three set tennis scoring system [15].

DEVELOPING OPTIMAL MATCH STRATEGIES

Croucher [16] summarizes much of the literature on developing strategies within current scoring in tennis and separates his analysis into firstly, serving strategies (given you have a first and second serve), secondly, the probability of winning a game, set or match, and thirdly, the analysis of match data. All involve mathematical and OR techniques.

Gale [17] used a simple mathematical model to identify the best first serve and the best second serve from a set of serves. Redington [18] concluded that in the 1971 Wimbledon final, Newcombe would have done better if he had served two first serves rather than a first and second serve. George [19] used a simple probabilistic model to show that a “strong” first serve followed by a weaker second serve was generally, but not always, the best strategy. Using considerably more data, King and Baker [20] came to the same conclusion. Hannan [21] proposed a game theory approach that factored in the opponents return while Norman [22] used dynamic programming to decide when a first serve should be used. With even more data, McMahon and de Mestre [23] also confirmed that the “strong weak” serve pattern was usually the best but were surprised at the number of matches where an alternative was better. Barnett and Clarke [24] used server and receiver statistics to predict strategies

and outcomes in any match between two players. Barnett and Pollard [25] adjusted this analysis for the effect of court surface. Pollard and Pollard [26] and Pollard [27] looked at the mathematical relationship between the probability a serve goes in and the probability a player wins the point and thus determined the optimal strategy for first and second serves. Barnett *et al.* [28] used the large OnCourt database (www.oncourt.info) to calculate match statistics for each court surface and thus determine service strategies to improve performance.

There has been much research over the years, including work by Fischer [29], Pollard [7], and Croucher [30] on the probability of winning a game, set (advantage and tie-break), and match where the probability of winning a point is constant for each player and each point is independent. For example, Croucher [30] calculated the probability that the server held serve from each of the 16 possible score lines. Morris [8] introduced the concept of the importance of a point defined as the difference between the two conditional probabilities that the server wins the game if he wins that point and the probability that he wins the game after losing that point. Morris showed that increasing the effort on the more important points and decreasing effort on the least important points increased the probability of winning. Pollard [10] expanded and generalized this analysis of importance and Barnett [31] showed numerically when a player should lift (increase) his/her probability of winning a point. Using 10 years of Grand Slam men’s singles data, Pollard, Cross and Meyer [32] showed that the better player had the ability to lift his play. Pollard and Pollard [33] used differential calculus to identify the points, games or sets when the player gets the most reward for lifting. All these mathematical analyses assume each point is independent of the previous points. However, using 4 years data from Wimbledon 1992–1995, Klaassen and Magnus [34] showed that points in tennis are neither independent nor identically distributed. Nevertheless, they claimed that these assumptions are “sufficient as a first order approximation,” which is similar to

Croucher's [16] comment that these assumptions "provided some interesting, if debatable, conclusions."

Brimberg *et al.* [35] addressed the problem of how to allocate your limited energy over (say) a first-to-three (best of five) set match. Using both probability and dynamic planning, they showed that where there are only two choices (high and base energy) it does not matter when the high energy is expended (although it does affect the expected length of the match). However, where there are three or more energy choices the player who is behind should divide his energy evenly over the remaining games but for the player who is ahead, it is best to divide his remaining energy between high and low rather than evenly.

Selected statistics (aces, double faults, winners, errors, total points) were often collected for selected important matches such as Davis Cup Challenge Rounds but were primarily for media use. For these and some of the earlier analyses above, data was laboriously collected by pencil and paper by someone watching the match or a video replay. In 1982, Bill Jacobsen began to record his son's matches on a micro computer. This soon developed into a system called *Compu Tennis* which became a useful tool for coaches. Today, the umpire records each point live into the computer and organizers record additional statistics at all Grand Slam matches and many matches on the Association of Tennis Professionals (ATP) and Women's Tennis Association (WTA) Tours, although only limited data is published and access to the data is restricted. By accessing Wimbledon data 1992–1995, Magnus and Klaassen (summarized in Ref. 36) were able to test and mostly refute some of the common hypotheses in tennis such as: any advantage in serving first, the first use of new balls, who has the advantage in the final set in a five set match, and even forecasting the winner before and at various stages during a match. The fact that their data is still being utilized demonstrates the limited access for researchers to officially collected data, although individual matches are provided to the media and selected match

statistics are available on the OnCourt database.

SURFACE OPTIMIZATION

Originally designed to be played on flat, manicured English lawn surfaces, British travelers soon took the game to Europe and the colonies and it spread quickly. Where suitable grass was not available, enthusiasts simply played on gravel, sand, asphalt, concrete, brick dust, and other surfaces. As technology developed, an increasing range of synthetic hard and cushioned acrylic surfaces as well as artificial grass and artificial clay surfaces appeared. The oldest and most prestigious tournament, Wimbledon (1877) has always been played on grass. The US Open (1881) was played on grass until 1974 when it was briefly played on clay, but was changed to hard court in 1977 at the request of the US players. The Australian Open (1905, although the Victorian Championships date back to 1880) was also played on grass until 1988 when it changed to cushioned acrylic (Rebound Ace) and since 2007 to cushioned hardcourt (Plexicushion). The French Open (1891) has always been played on clay (crushed brick) but was restricted to French players until 1925. The importance of these four Grand Slam tournaments ensures most other tournaments and venues use the same or similar surfaces.

Further, court surface has a very significant effect on the nature of the way the game is played, so that, for example, selection of court surface is a prized home ground advantage in the Davis Cup. Selection of court surface for a tennis facility is a multicriteria optimization problem where the capital cost of construction, maintenance costs, and player preferences in terms of court speed and comfort are some of the factors to be considered. Tennis Australia has introduced a Court Rebate Program to encourage clubs to lay the surfaces used at the Grand Slams rather than the popular synthetic grass surface.

The rules of tennis were effectively silent on court surfaces, but to allow quantification

of the speed of a court surface, the ITF has developed a Court Pace Classification Program [37]. This system divides court pace as measured by the Court Pace Rating (CPR) into five categories:

Category 1 (slow pace)	CPR 0–29
Category 2 (medium slow)	CPR 30–34
Category 3 (medium)	CPR 35–39
Category 4 (medium fast)	CPR 40–44
Category 5 (fast)	CPR 45 and over

and nine court surface types:

A	Acrylic
B	Artificial clay
C	Artificial grass
D	Asphalt
E	Carpet
F	Clay
G	Concrete
H	Grass
J	Other (e.g., modular tiles, wood, canvas)

Currently, 57 different court surface suppliers are recognized by the ITF and their products cover 11 (Category 1), 15 (Category 2), 43 (Category 3), 38 (Category 4), and 26 (Category 5) surfaces. However, few companies laying clay or grass courts register as their products are inherently variable, although in general they are recognized as slow and fast respectively.

Barnett and Pollard [25] analyzed the performance of players on grass, hard, and clay courts used on the ATP and WTA Tours, and how the changing number of tournaments on each surface, especially the decline in grass courts, affects player rankings and also injuries. Only Wimbledon (grass) modifies official rankings when doing seedings

for its Championships. Rankings and medical risks are discussed later, but both would benefit from further OR analysis factoring in the effect of court surface.

The development of a court pace classification program has been an interesting technical, scientific, and statistical exercise [38], especially since 2008 when the ITF introduced rules to limit the ability of home nations to select extreme surfaces for the Davis Cup Competition. However, player comfort has not been subject to any attempt at classification.

OPTIMIZATION OF BALL CHARACTERISTICS

Compared to the technological development of the golf ball over the past 100 years, the tennis ball has remained almost unchanged except for the development of the pressurized can, to ensure longer shelf life, and the change in color from white to yellow. Pressureless and high altitude balls are also available which differ from the “standard ball” by virtue of their internal pressure and bounce height.

Over the last decade, the ITF has tried to address the issues of court speed and style of play by encouraging manufacturers to make three types of balls, where ball type one (fast speed ball) is designed for use on slow paced court surface; ball type three (slow speed ball) is designed for use on fast paced court surfaces, while the standard ball type two (medium) is designed to be used on medium-slow, medium and medium-fast surfaces (i.e., the majority of courts). While there is clear evidence that using the appropriate ball on the relevant surface makes the game easier to play (for both players), the use of balls other than ball type two is limited.

Brody *et al.* [39] have a number of chapters devoted to the tennis ball and the testing of ball properties for perfect bounce, ball spin, trajectories, and similar technical characteristics. All ITF ball testing measures the properties of new balls only. The ITF Technical Department has now revolutionized ball approval by introducing the testing of ball durability into the process. A key challenge has been to accurately simulate in the laboratory the effects of play on the ball [40].

Another development is the comparison between the static stiffness of tennis balls as measured in ITF ball testing and the dynamic stiffness in real play [41], the potential outcome of which is the introduction of approval tests that are more representative of player perceptions of ball properties.

Special tennis balls have been developed to make it easier for starter players, especially 10 and under, to play the game and to position tennis as easy and fun. These introductory balls are color coded into red (stage 3), orange (stage 2), and green (stage 1) and are officially tested for approval by the ITF.

OPTIMIZATION OF RACKET CHARACTERISTICS

For nearly 100 years, tennis rackets were made of wood and generally strung with strings made from sheep's gut. Aluminum frames appeared in the 1960s leading to the larger head size in the 1970s. Aluminum was replaced with graphite and then by composite rackets made mainly from carbon fiber reinforced with graphite. Titanium and more recently ceramic fibers, boron, and other products, in many cases, outcomes of the research and development in the aerospace industry, have also been used.

Comparing modern carbon fiber composite rackets to the best wooden rackets at the beginning of the open era shows they are much lighter (180–350 g compared to 370–425 g), longer (68–73 cm compared to 66–68 cm) with a larger head size (580–870 sq. cm compared to 420–450 sq. cm). Amongst the top 20 male players, Warinka uses a 271-g racket while the average racket weight is 320 g. Amongst the top 20 women players, the Williams sisters use 270-g rackets while the average racket weight is 305 g.

The modern composite rackets have a greater “sweet spot” and are considerably more “powerful.” The term *sweet spot* is the commonly accepted term for the area on the racket face where the impact feels best, generally the node point since there are no vibrations. In fact, the “sweet spot” can be any of three spots; the center of percussion

where shock (i.e., acceleration) of the racket is minimized, the node where vibration is minimized and, finally, the location of maximum ball rebound speed, although the impact at this point does not necessarily feel “sweet.” On service, top players serve from near the top of the racket due to the added height advantage and the faster racket speed at the top.

Inherently, the material of which modern rackets are made are more powerful than wood; in that, less energy is lost (due to bending) during impact. On the assumption that a player puts constant energy into a stroke, a modern (lighter) racket will have a greater impact speed and will therefore generate a higher ball speed, which is used as the definition of “power.” In theory, lighter rackets should be less powerful than the older heavier rackets. But swing speed (inversely related to mass) is more important, so you can generate more ball speed with a lighter racket. Stiffness of racket material has an effect, but not to the same extent as mass and swing speed.

At the social level, larger rackets have made the game easier to play by being more “forgiving” to off-centre impacts. At the elite level, they have changed the way the game is played (technique) and professional tennis is now a considerably faster and different game as compared to that of the amateur era.

Strings and stringing have also contributed to the development of the modern racket. Until the 1940s, all rackets were strung with gut strings but gradually nylon strings appeared, although nylon was inferior to gut in the wood rackets. The development of the modern composite rackets and the considerable improvement in strings with nylon, polyester, kevlar, and other substances means that, today, there is little difference between different string types and all are used by the top professional players, with polyester being the most preferred string followed by gut and then nylon. Polyester strings do generate more spin [42].

But it was the method of stringing that led the ITF to finally act in 1978 on the definition of the racket when “double stringing” or “spaghetti stringing” allowed some players to

generate so much spin that the ball was virtually unplayable. Such stringing was banned. In the 1980s, the increasing size of the racket led the ITF to finally limit the size of a tennis racket in the Rules of Tennis and to define the parameters for stringing patterns.

In the 1990s, the ITF established a research laboratory at its headquarters in London with the analysis of rackets and strings and the increasing power they can generate being a major issue for ongoing research and for the possible introduction into the rules of tennis [43].

Brody *et al.* [39] have a number of chapters devoted to the tennis racket and the technical measurement of relatively simple characteristics such as head size, weight, and grip size, through to the more complicated characteristics of frame stiffness, balance point, sweet spot, swing weight, stability, shock, vibration, feel, and power.

As part of its role to preserve the nature of tennis, the ITF Science and Technical Department has developed a software program which simulates the effects of ball, racket and surface properties, and atmospheric conditions on ball trajectory for any stroke. Not only is the software (known as *Tennis GUT*) able to establish the effects of any combination of equipment on the nature of the game, but it also allows the user to modify the properties of that equipment. Trends in equipment design and properties can be used, for example, to predict future properties and, as a consequence, to predict how these trends may affect the way the game is played.

OPTIMIZATION FROM A COACHING PERSPECTIVE

Coaching is the method by which one generation passes on its considerable knowledge, experiences, and expertise to the next generation, thus enabling the game to grow and develop. In tennis, coaches play a significant role at every level from introducing youngsters to the game and teaching them the basic rudiments of how to play, through to helping the world's best player to become even better and retain his/her number one

ranking. This includes analyzing each opponent to detect any potential weakness that might be exploited.

Traditionally, tennis coaching involved either past champions describing their experience and how they played the game or other teachers, who may not have had the same on-court success, but who appreciated and understood the style and technique of the champions and had the ability to describe and teach it. While there is still a role for the traditional coach, the modern coach also makes considerable use of all the sports science and technology that have been introduced into the game over recent decades.

Coaching courses today include a significant component of sports science and technology and coaches are encouraged to access the ITF publications and the ITF coaching website www.tenniscoach.com to see the extent of modern technology available and to engage in on-line learning or upgrading. The ITF has recommended syllabi for level one, two, and three coaches that are available in a number of languages and which are now used in over 80 countries.

Many coaches use video players to record their pupil in practice or match conditions and then use software such as Dartfish to analyze their game. Other match and player analysis programs commercially available include the Swinger video analysis, Chart-Mate Pro, and Stats Master video analysis. Player match statistics are available on the OnCourt website www.oncourt.info allowing players and coaches to analyze their performance and that of their next opponent.

For running their businesses, coaches use specifically designed commercial programs such as Tennis Biz, Tennis Logic or Software Management Solutions. For marketing and communications purposes, there is increasing use of SMS, e-mail, and in some cases, their own website.

National associations use products such as Athlete Management System to track all players in their academies. Coaches record their analysis following matches, practice sessions, training regimes, technical advice, injury, periodization plans, communication

with other coaches, and even video footage and analysis.

Using Wimbledon singles data 1992–1995, Klaassen and Magnus [44] converted player rankings into the probability a particular player won a match between two players. They then recalculated that probability as the match progressed. They suggested such information was most useful for television commentators rather than coaches, but obviously also for punters and betting agencies. For further probability predictions, see Bedford and Clarke [45] and Barnett and Clarke [46].

OPTIMIZING PLAYER TECHNIQUE

Biomechanics is the study of human movement. In tennis, this involves the search for the optimum playing technique, the most efficient and effective combination of power and control in both stroke and movement while minimizing the risk of injury.

Traditionally, coaches performed this task simply by observing the world's best players and then trying to teach these observed techniques to their pupils. But tennis is such a multidimensional sport. It is played by men and women, young and old, clumsy and talented, serve/volley players and baseliners and with ever changing equipment on a wide range of surfaces from clay (slow) to hard courts (medium) to grass (fast). There is no single optimum way to play and champions have displayed a wide range of styles and techniques. However, modern technology has made it easier to describe body movement, to quantify movement, and to compare players' style.

Elliott and Reid [47] give a good summary of the wide range of descriptive and objective technologies now available to the coach or the tennis biomechanical researcher. Generally they involve one or more high speed video cameras linked to a computer loaded with one of the increasing range of sport analysis software packages. However, they repeat the warning of Elliott and Knudson [48] that any recommendation by a coach to change a player's game first needs a comprehensive assessment of a wide range of other player characteristics.

For a complete study of the biomechanics of advanced tennis with respect to the effectiveness and efficiency of a player's on-court movement and stroke production, and the relationship with performance enhancement and injury prevention, the reader is referred to the ITF publication, *Biomechanics of Advanced Tennis* [49] and its wealth of references.

MINIMIZING MEDICAL RISK

Sports medicine has become a legitimate and recognized discipline within medicine. Basically, it involves the prevention of athletic injuries or their detection, treatment and rehabilitation. It is closely linked to the other sports sciences, although in most countries only medical practitioners are licensed to approve drugs as part of the treatment. There are now doctors who specialize in injuries specific to tennis. The WTA and ATP are in the process of introducing an injury registration database which will provide accurate data on tennis injuries in the future, leading to opportunities for statistical and OR analysis not previously available.

The best known injury in tennis is the so-called tennis elbow. Many people acquiring tendonitis of the elbow from other causes unrelated to tennis will still call the injury "tennis elbow." The different injuries causing elbow pain and their diagnosis, treatment and rehabilitation are described by Renstrom [50].

The International Olympic Committee and the International Tennis Federation, together with the Society for Tennis Medicine and Science and the ATP and WTA Tours, have combined to produce a *Handbook of Sports Medicine and Science in Tennis* [51]. The nature of the game means that injuries occur throughout the whole body with shoulder, back, ankle, and knee being the most common sites of injury, but these are generally minor injuries that respond well to treatment. The majority of injuries are due to microtrauma repetitive overwork. Macrotrauma, such as sprains or fractures, does occur in a minority of cases and are difficult to prevent with training activities.

Although injuries do occur, Pluim *et al.* [52] have conducted an extensive literature search of the health benefits of tennis and concluded that “people who choose to play tennis appear to have significant health benefits, including improved aerobic fitness, a lower body fat percentage, a more favorable lipid profile, a reduced risk for developing cardiovascular disease, and improved bone health.”

Other aspects of sports science and medicine currently undergoing research, analysis, progressive introduction or modification, include minimum age limits for boys and girls for international tournament play, continuous registration of injuries and their treatment for international players, measurement of heat and humidity and appropriate rules affecting play in extreme conditions, and, finally, antidoping. Data now being collected will provide considerable opportunities for research on each of these aspects.

Tennis has an Antidoping Program [53] to maintain the integrity of the sport and to protect the health and rights of all tennis players. The ITF is a signatory to the World Antidoping Code. Any player who participates in an event organized, sanctioned, or recognized by the ITF, ATP or WTA Tours is subject to In-competition and Out-of-competition testing under the program.

Statistics is commonly used in “Tennis Medicine.” For example, Hatch *et al.* [54] report an experiment in which 16 asymptomatic Division I and II collegiate tennis players performed single-handed backhand ground strokes with rackets of three different grip sizes (recommended measurement, undersized 1/4 in., and oversized 1/4 in.).

However, Pluim *et al.* [55] have concluded that there have been few longitudinal cohort studies that have investigated the relationship between risk factors and injuries in tennis. This, together with the complete absence of randomized control trials concerning injury prevention, means that this is an area that is desperately in need of more rigorous analysis in the future.

Other useful references to sports medicine in tennis include Pluim and Safran [56] and Petersen and Nittinger [57] while coaches

are referred to the ITF Manual on Tennis Medicine for Tennis Coaches [58].

EFFICIENT TOURNAMENT MANAGEMENT

Most components of the work required for the running of a successful tournament have been gradually converted from long hours and substantial paperwork to computer assisted administrative systems such as CAT (Computer Assisted Tournaments), TMS (Tournament Management Systems), and TP (Tournament Planner). As explained by Della Croce *et al.* [59] the goal is to maximize the number of feasible matches, given the constraints in terms of court and player availability.

The world’s first tournament to be managed with the aid of computer software (CAT) was in Hay, Australia in October 1980. This first version of CAT was designed to produce the daily schedule for each player competing in up to five or six events in a 3-day country tournament. The current version handles virtually all aspects of tournament management.

In the 1990s, the Americans introduced a similar product called TMS for which the US Tennis Association purchased a nationwide license. Many other countries followed the United States making TMS the most popular program for tournament management for some time.

The most recent tournament management software, TP, was introduced by the Dutch and adopted in 2007 by the ITF for management of all its tournaments worldwide. Its wide range of features and flexibility means that it has been adopted for small tournaments through to Grand Slams (e.g., Australian Open 2009).

The ITF has recently introduced a compulsory International Player Identification Number (IPIN) and an associated on-line player entry system that, in 2009, covers tens of thousands of players in well over one thousand tournaments on the ITF Junior Circuit, ITF Pro Circuit, and ITF Seniors Circuit. This allows the on-line scheduling of a worldwide calendar of tournaments, permitting players

to easily select their most appropriate tournament at any time according to their ranking and the entry decisions of other players.

STRENGTHENING THE MENTAL SIDE OF THE GAME

Sports psychology deals with the mental side of tennis and covers the study of human behavior within the context of the game of tennis. Many matches are won or lost because of the mental differences between the two players rather than any technical or physical difference.

The role of psychology in tennis is summarized in the comprehensive book *Tennis Psychology* by Crespo *et al.* [60] including over 200 references on playing with confidence, playing in “the zone,” “choking,” lack of concentration, burnout, motivation, fear of losing or winning, or simply how to play matches the same way as you play in practice. This book published by the ITF gives over 200 on-and off-court psychological training techniques, drills, and activities to strengthen the psychological approach of players to match play.

But as noted by Forzoni [61] and Calstedt [62], because it deals with peoples’ minds, sport psychology does not have the same degree of objective measurement as the physical and technical side of the game. But both these authors also recognize that with technological advances, decreasing costs, and decreasing size of equipment, along with the ease of use of biofeedback and neurofeedback devices, it is becoming easier to measure and monitor over time the effectiveness of specific mental skills strategies. This will lead to opportunities for statistical and OR studies to minimize fluctuations in performance during a match and to optimize mental skills.

Emotions being experienced during a game of tennis have an effect on the human body and some aspects can be measured. Forzoni [61] strongly recommends the Heart Math Freeze Framer which measures an athlete’s heart coherence under various situations, so that with various relaxation techniques (controlled breathing, visualizing positive images) you can learn to control

your heart coherence and consequently your emotions. Calstedt [62] suggests that the most reliable indication of psychological states in athletes is heart rate variability, or heart rhythms, which can be measured by electrocardiograms or pulse wave recordings. He recommends that players should learn techniques to control their heart rhythms and consequently their emotions. He has developed the Calstedt Protocol as one possible approach for athlete psychological assessment, mental training, and interaction efficiency.

ACCURATE RANKING OF PLAYERS

In 1973, the leading male tennis players formed their own union, the ATP, and one of their first acts was to introduce a 12-month weighted moving average computing rankings system to determine fairly which players gained entry into tournaments worldwide and to determine which players were seeded. A separate doubles ranking was introduced in 1976. The WTA was also founded in 1973 and introduced its computer rankings system in 1975.

Prior to this time, entry into tournaments and seeding was done by the tournament director or tournament committee. National rankings were compiled annually by national tennis associations. World rankings were generally announced by various journalists so there were many unofficial world rankings and no official world ranking.

Under the original ranking systems, tournament importance or “strength” was determined by prize money and player performance was measured by the round reached. A schedule of points was agreed based on the above and a player’s ranking was calculated as the average points earned for tournaments played in the previous 12 months. Utilizing the capacity of a computer to create a more rigorous ranking, Musante and Yellin [63] were able to rank the strength of tournaments by the ranking of all players entered in that event and, also, to measure performance using the ranking of defeated opponents, not just the round reached. The concept of bonus points for defeating a higher

ranked player was used by the WTA for some years, but was subsequently discontinued. The ATP publishes a calendar year race to the ATP finals as well as the normal ranking on performances over the past 12 months.

Subsequently, Blackman and Casey [64] recognized that previous rankings were useful for determining tournament entry for players and for tournament seedings, but not for determining match result probabilities, betting odds, and equitable handicapping methods. Using the actual scores in all matches between the players being ranked, they developed a rating in numerical units similar to a golf handicap. The difference in these rating units for any two players was shown to be a very good indication of match result probabilities and could also be used to determine what handicap should be given to the weaker player to make the match more even. See also Klaassen and Magnus [44], Bedford and Clarke [45], and Barnett and Clarke [46] discussed earlier under the section on coaching.

In 1989, the ATP players union combined with the tournaments (excluding ITF and Grand Slams) to form the ATP Tour. Likewise in 1995, the WTA Players Association combined with the Women's Tennis Council (including ITF and Grand Slam) to form the WTA Tour. Since then, both computer rankings have rewarded quantity as well as quality by selecting a player's best results from a minimum number of tournaments, with the ATP Tour and WTA Tour, and the ITF for junior and senior rankings all using different formulae. Only the ITF uses one ranking for each player based on both singles and doubles matches.

Mathematicians could clearly develop a ranking or rating system superior to any of those currently used by tennis governing bodies but the players and tournaments prefer simplicity and are reluctant to make changes to their current systems.

IMPROVING OFFICIATING

A game of singles in tennis involving two players can involve no umpire, one central chair umpire or up to 12 officials (center

chair plus up to 11 lines persons) making tennis one of the most highly officiated sports. The largest tournaments, the Grand Slams, require a team of 350 officials, gradually reducing in numbers as players are eliminated.

Clay courts have always had the advantage of the ball leaving a mark which can be examined if there is a dispute over a line call. Ball mark inspection procedures are included as an Appendix to the Rules of Tennis [1].

The first technical development to assist line calling was the "Cyclops" machine which served tennis for 20 years. It was only used on the service line and involved sending beams of light either side of the service line to detect whether the service was in or out of play.

The first attempt to cover the whole court was the TEL machine which involved an undetectable modification to the ball (iron particles in the cover) and placing wires in the court on either side of the line to detect whether a ball that bounced close to the line was either in or out. It was successfully used for one year at the Hopman Cup with a center chair and no linesmen, but the cost, standby arrangements (still needed to keep linemen on call in case of failure), and the need to dig up the court for installation, limited its use.

The Auto-Ref and Hawkeye optical tracking system takes a different approach to line calling. These systems track the flight of a tennis ball with software being used to map the point of impact relative to the lines. As explained by Szimák *et al.* [65] the software uses pattern recognition and other algorithms to find the ball when it is hit over the net, to convert 2D to 3D images, estimating the ball trajectory and predicting where the ball will intersect with the court surface.

Originally introduced as an aid to television coverage, by increasing the number of cameras and other technical improvements, the ITF Technical Department gave approval for Hawkeye's use for officiating in tournament play. Electronic review procedures are also included as an appendix to the Rule of Tennis [1].

Research continues into other technical systems to assist in-line calling including

heat sensors (infrared cameras recording the heat generated when a ball bounces).

Mathematical modeling and statistics have been used extensively in the development of the above and other line-calling systems. For example, Jonkhoff [66] used experimental data to show that electronic line-calling using the TEL system is consistent and accurate and also cheaper than line umpires. Marshall [67] showed that the multibeam LineHawk provided superior accuracy than a single master beam. However, Collins *et al.* [68] have expressed concerns at the way Hawkeye decisions are naively accepted although the technology is certainly not perfect. They suggest that measurement error needs to be made salient and that confidence levels should be attached whenever ball impacts are reconstructed. The average accuracy is about 5 mm but players accept the machine-made decision over a human decision. Mather [69] has used Monte Carlo simulation to show that, for the best-fitting space constants, the condition for a challenge (player and umpire disagree) was met in 20.8% of all trials. In 39.6% of the simulated challenges, a line judge error was recorded, which is very close to the 39.3% of errors found in the actual challenge records.

At www.freepatentsonline.com/5908361.html details of a new line-calling invention (Automated tennis line-calling system: US Patent 5908361) were reported on March 20, 2009. This invention uses mathematical models to merge information from loudspeakers, ball impact sensors close to boundary lines, and pressure sensing devices to make line calls and foot fault calls. Foot faults are detected by comparing (i) the time of occurrence obtained from signals induced by contact of the serving player's foot on a pressure sensor at the baseline with (ii) the computed time of occurrence of racket contact with the ball as derived from the racket sounds received by three or more microphones. This system can also be used to monitor the progress of play and to keep score using the sequence of locations of ball bounces, net-cord hits, service foot faults, and racket hits. In particular, player statistics such as ball speed on service,

winners, errors, and other measures of player accuracy and effectiveness can be compiled from this data.

This is clearly an area of great potential for further research using management science and operations research methods along with technical development.

CONCLUSION

Technical development has already been made and will continue to make a significant contribution to the development of the game and the way it is played, managed, and viewed. The challenge is to maintain the integrity of the sport while keeping it relevant in the twenty-first century. In this introductory article, it has been shown that in this context there is plenty of scope for OR and MS methodologies because the technical developments are allowing more scientific measurement of the important decision-making variables and constraints.

For a more extensive list of scientific tennis articles than included here, the ITF web site www.itftennis.com/coaching/publications contains hundreds of articles in categories including sports science, biomechanics, medicine and conditioning, psychology, and technique and methodology.

Acknowledgment

We would like to express our appreciation to Stephen Clarke, Dave Miley, Stuart Miller, and Graham Pollard for their advice and comments on sections of this article and the referees for their constructive suggestions.

INTRODUCTION

Following [1], the pairwise comparison method was introduced in a rudimentary form by G.T. Fechner [2] in 1860, and it was formalized first by L.L. Thurstone [3] in 1927. The method has been a basic ingredient of several interactive multicriteria methods with many applications reported in several areas such as forecasting, investment decision, projects of national importance, and other socioeconomic planning issues.

The basic idea underlying the pairwise comparison method is simple and very close to common sense. Thus, let us assume a scenario where there is a set A of n objects $\{a_1, a_2, \dots, a_n\}$, such as criteria and alternatives, to be evaluated by a single decision maker (DM). If the cardinality of set A or the number n of objects is relatively large, it is very difficult for the DM to provide global preferences for the n objects; that is, to compare simultaneously the characteristics of n objects. However, if we establish a partition of the set A into subsets of cardinality two, such as:

$$\{\{a_j, a_k\}\}_{j,k=1,\dots,n}$$

then, we are demanding from the DM a local information much easier to provide and likely much more robust than the global information. In short, the main virtue of the pairwise

comparison procedure is its simplicity, which is close to the limited human cognitive capacities: **“take two parts at a time when the whole is too difficult to handle simultaneously, especially when the whole is a large one.”**

The final purpose of the pairwise comparison method is to deduce a set of numerical values $(w_1, w_2, \dots, w_n)$ representing the relative importance of each object for the DM. This fact implies that a generic element of the pairwise comparison matrix, m_{ij} , is expected to be equal to the ratio w_i/w_j . For this reason, an ideal pairwise comparison matrix is expected to verify the following properties:

- Reflexivity: $m_{ii} = 1 \forall i$
- Reciprocity: $m_{ij} \times m_{ji} = 1 \forall i, j$
- Consistency: $m_{ij} \times m_{jk} = m_{ik} \forall i, j, k$

These three properties define the concept of rational DM during a pairwise comparison process. However, it is an empirical issue that, in practice imperfect judgments due to human cognitive limitations, leads to matrices without these ideal properties. The challenge faced is how to deduce the priority weights when different scenarios of rationality are verified. This challenge has been addressed by following these two directions: when we state “*a priori*” hypothesis about the rationality of the DM, or when the rationality study is made “*a posteriori*”; that is, when a complete pairwise comparison matrix has already been obtained. These two directions define sections titled “Deriving Priority Weights with Hypotheses about the DM Rationality” and “Deriving Priority Weights Without Making any Hypothesis about the DM Rationality” of the article, respectively.

Finally, in order to illustrate how the pairwise comparison method works and how the corresponding pairwise comparison matrices are obtained, we shall resort to a simple example. Thus, let us assume that in a hypothetical civil engineering project, a DM must provide preferential information with respect to three relevant criteria in the

decision-making process: cost (C), environmental impact (EI), and energy consumption (EC) associated with the undertaking of the project. For this particular example, a pairwise comparison procedure requires for this particular example six judgment values (in general $n(n-1)$) from the DM, which lead to the following square matrix:

$$\begin{array}{c} \text{C} \quad \text{EI} \quad \text{EC} \\ \text{C} \quad \begin{pmatrix} 1 & m_{12} & m_{13} \\ m_{21} & 1 & m_{23} \\ m_{31} & m_{32} & 1 \end{pmatrix} \\ \text{EI} \\ \text{EC} \end{array}$$

The interpretation of the elements of the above matrix is straightforward. For instance, the element m_{12} represents the relative importance attached by the DM to the criterion cost when it is compared with the criterion environmental impact. It is now clear that the pairwise comparison matrix will be worthy only if a cardinal information/numerical value is associated with its elements and obviously, for that, we shall need a numerical scale. Without loss of generality in this article, we shall resort to Saaty's scale, a widely used scale in the applied literature [4].

DERIVING PRIORITY WEIGHTS WITH HYPOTHESES ABOUT THE DM RATIONALITY

This issue will be addressed by considering three different possible scenarios according to the level of rationality underlying the information provided by the DM.

Case I. Rational Decision Maker

In this scenario of perfect rationality, we assume that the information provided by the DM holds the three properties: reflexivity, reciprocity, and consistency. Except for small problems, this scenario is unrealistic, but it has theoretical interest as a starting point for the presented analysis.

In this context, the DM only needs to provide $(n-1)$ comparisons. Moreover, it is mathematically quite simple to derive the vector of preferential weights w from matrix M . Thus, for the above simple example in this

scenario, the vector w would be obtained by solving the following system of homogeneous equations:

$$\begin{aligned} w_1 - m_{12}w_2 &= 0 \\ w_1 - m_{13}w_3 &= 0 \\ w_2 - m_{23}w_3 &= 0 \end{aligned}$$

The consistency condition guarantees that the rank of the matrix of coefficients is less than the number of unknowns, which implies the existence of a nontrivial solution for the above system of equations. Moreover, the reciprocity condition avoids the inclusion of the three equations corresponding to the lower part of the matrix.

Case II. Partially Rational Decision Maker

In this new scenario, the rationality conditions are relaxed by eliminating the consistency condition. Now, the DM holds the tautological condition of reflexivity (i.e., one object is of the same importance as itself) and the reciprocity condition. In this new scenario, the number of pairwise comparisons increases from $(n-1)$ to $n(n-1)/2$. Thus, for our simple example with three objects, we will now require three pieces of information instead of two. This small difference is due to the small cardinality of the set A of objects. If, for example, the DM needs to compare 10 objects, the number of pairwise comparisons will move from 9 to 45, which is a significant difference.

As we are now assuming that the consistency matrix does not hold, the system of homogeneous equations only has as a solution the trivial one (i.e., $w_1 = w_2 = w_3 = 0$). There are several procedures for approximating a solution to the corresponding system of equations. The theory attempts to provide a consistent matrix "as close as possible to" M . One of these procedures was proposed by Saaty [4] in 1977. With this method, the original matrix M is replaced by a consistent matrix $C = (c_{ij} = v_i/v_j)_{ij}$, where $v = (v_1, v_2, \dots, v_n)$ is the eigenvector associated with the largest eigenvalue of M . By the theorem of Perron–Fröbenius,

$\lambda_{\max}$ is unique, positive, and simple. Furthermore, v can be chosen as having all its positive coordinates. Now, the consistent matrix C shares the eigenvector v with the inconsistent matrix M . In this sense, it can be considered that C is “as close as possible to” M .

Another family of procedures is based on the idea of approximating a solution to the above system of homogeneous equations by transforming the systems into a goal programming (GP) formulation. There are many variants in this direction; see [5] or [6]. The most straightforward GP formulation of our problem leads to the following weighted GP formulation:

Achievement function:

$$\text{Min } n_1 + p_1 + n_2 + p_2 + n_3 + p_3$$

Goals:

$$w_1 - m_{12}w_2 + n_1 - p_1 = 0$$

$$w_1 - m_{13}w_3 + n_2 - p_2 = 0$$

$$w_2 - m_{23}w_3 + n_3 - p_3 = 0$$

Auxiliary constraint:

$$w_1 + w_2 + w_3 = 1$$

Nonnegativity constraints:

$$n_i, p_i, w_i \geq 0 \quad i = 1, 2, 3$$

The last equation of the above GP model has an auxiliary character, making the interpretation of the weights as percentages of importance easier, and also preventing the optimal solution from being arbitrarily scaled. It is interesting to note that the value of the achievement function for the optimum solution will indicate the level of consistency associated with matrix M . This matter will be clarified later with the help of a numerical example.

Case III. Irrational Decision Maker

In this new scenario, the only rationality condition is the tautological condition of reflexivity. Therefore, the number of pairwise comparisons requested is now $n(n-1)$; that is, the removal of the reciprocity condition implies doubling the number of questions raised from the DM. Moreover, in a scenario of nonreciprocity, the maximum eigenvalue method does not work. However, the family of procedures based on GP is straightforwardly applicable to this scenario. In this case, the GP model will now have double the number of equations (goals) with respect to the previous case. Thus, the general weighted GP model to derive the vector of weights for a general pairwise comparison matrix of dimension 3×3 , without enjoying properties of consistency and reciprocity will be given by:

Achievement function:

$$\begin{aligned} \text{Min } n_1 + p_1 + n_2 + p_2 + n_3 + p_3 \\ + n_4 + p_4 + n_5 + p_5 + n_6 + p_6 \end{aligned}$$

Goals:

$$w_1 - m_{12}w_2 + n_1 - p_1 = 0$$

$$w_1 - m_{13}w_3 + n_2 - p_2 = 0$$

$$w_2 - m_{21}w_1 + n_3 - p_3 = 0$$

$$w_2 - m_{23}w_3 + n_4 - p_4 = 0$$

$$w_3 - m_{31}w_1 + n_5 - p_5 = 0$$

$$w_3 - m_{32}w_2 + n_6 - p_6 = 0$$

Auxiliary constraint:

$$w_1 + w_2 + w_3 = 1$$

Nonnegativity constraints:

$$n_i, p_i, w_i \geq 0 \quad i = 1, 2, 3$$

If we represent $\text{Min} \sum_{i=1}^6 (n_i + p_i)$ by θ and $\text{Max} \sum_{i=1}^6 (n_i + p_i)$ by θ' , the index of consistency (IC) associated with the solution of the above GP model will be equal to:

$$\text{IC} = [1 - (\theta/\theta')] \times 100$$

as θ' measures the maximum possible level of inconsistency (see the numerical example below).

Numerical Example

The above ideas will be illustrated with the help of the following example. For an exercise with four objects, Saaty's scale, without the reciprocity property, has been used for valuations, yielding the following pairwise comparison matrix, which is nonreciprocal and inconsistent:

$$\begin{pmatrix} 1.00 & 5.00 & 0.50 & 3.00 \\ 0.25 & 1.00 & 3.00 & 0.33 \\ 2.00 & 0.50 & 1.00 & 0.50 \\ 0.33 & 3.00 & 2.00 & 1.00 \end{pmatrix}$$

The vector of preferential weights corresponding to the above pairwise comparison matrix can be obtained by solving the following weighted GP model:

Achievement function:

$$\begin{aligned} \text{Min} \quad & n_1 + p_1 + n_2 + p_2 + n_3 + p_3 + n_4 \\ & + p_4 + n_5 + p_5 + n_6 + p_6 + n_7 \\ & + p_7 + n_8 + p_8 \end{aligned}$$

Goals:

$$\begin{aligned} w_1 - 5w_2 + n_1 - p_1 &= 0 \\ 2w_1 - w_3 + n_2 - p_2 &= 0 \\ w_1 - 3w_4 + n_3 - p_3 &= 0 \\ 4w_2 - w_1 + n_4 - p_4 &= 0 \\ w_2 - 3w_3 + n_5 - p_5 &= 0 \\ 3w_2 - w_4 + n_6 - p_6 &= 0 \\ 2w_3 - w_2 + n_7 - p_7 &= 0 \\ 2w_3 - w_4 + n_8 - p_8 &= 0 \end{aligned}$$

Auxiliary constraint:

$$w_1 + w_2 + w_3 + w_4 = 1$$

Nonnegativity constraints:

$$n_i, p_i, w_i \geq 0 \quad i = 1, 2, 3, 4$$

It should be noted that, in order to avoid redundancies, in the above model, the equations corresponding to reciprocal elements have not been replicated. By solving the model, the following solution is obtained:

$$\begin{aligned} w_1 &= 0.612, w_2 = 0.122, w_3 = 0.062, w_4 \\ &= 0.204 \end{aligned}$$

For this solution, $\theta = 1.59$ and $\theta' = 8.01$. Therefore, the consistency of the solution obtained, according to the index IC previously defined, is equal to:

$$\text{IC} = [1 - (1.59/8.01)] \times 100 = 80.14\%$$

DERIVING PRIORITY WEIGHTS WITHOUT MAKING ANY HYPOTHESIS ABOUT THE DM RATIONALITY

In this scenario, we have had to obtain the complete pairwise comparison matrix;

that is, the number of pairwise comparisons requested is $n(n-1)$, similar to case III of section titled “Deriving Priority Weights with Hypotheses about the DM Rationality”.

We consider that, in practice, imperfect judgments, due to the human cognitive limitations, lead to matrices with a high level of violation of the rationality properties defined earlier. This challenge has been addressed in the literature by following one of the following three directions:

- (a) A threshold of inconsistency is defined in one way or another. Matrices surpassing this threshold, as they are derived from highly inconsistent information, are eliminated from the analysis. This is a clear normative approach.
- (b) The inconsistency is considered to be a fact. As the information is provided by a real DM, it must be considered in the analysis. This approach can be considered to be a positive or descriptive one. In this case, the scenario is similar to the one stated in case III of section titled “Deriving Priority Weights with Hypotheses about the DM Rationality”.
- (c) An approximation perspective, which can be considered as a prescriptive orientation; that is, a compromise between the above normative and descriptive orientations. With this perspective, when there are inconsistencies, a new matrix M' that differs from M “as little as possible” and that holds the rationality conditions “as much as possible” is sought, see [7, 8], or [9]. This is the scenario in this section.

According to the third direction, and in order to obtain the new matrix $M' = (m'_{ij})_{ij}$, it is interesting to review a general procedure based on a distance function framework [10]. For this purpose, the following objective functions are introduced for a general metric $p \in [1, \infty)$.

- (a) *Imposing similarity between matrices M and M' .* Imposing similarity between

matrices M and M' implies the minimization of the following nonlinear function.

$$\sum_{\substack{i,j \\ i \neq j}} |m_{ij} - m'_{ij}|^p$$

- (b) *Imposing reciprocity to matrix M' .* Imposing reciprocity in matrix M' implies the minimization of the following nonlinear function.

$$\sum_{\substack{i,j \\ i \neq j}} |m'_{ij} \times m'_{ji} - 1|^p$$

- (c) *Imposing consistency to matrix M' .* Imposing consistency in matrix M' implies the minimization of the following nonlinear function.

$$\sum_{\substack{i,j,k \\ i \neq j \neq k}} |m'_{ij} \times m'_{jk} - m'_{ik}|^p$$

The optimization of the above objective functions is subjected to the fulfillment of certain scale conditions used in the pairwise comparison procedure. This consideration leads to the following constraints set:

$$L \leq m'_{ij} \leq U \quad \forall i, j$$

The nonsmooth character of the above objective functions makes their optimization extremely difficult. However, this type of optimization problems can be reduced to GP formulations considering the relationship between distance function models and mathematical programming [11]. Thus, the above objective functions can be simultaneously optimized in an aggregated way by formulating and solving the following Archimedean GP model:

Achievement function:

$$\begin{aligned} \text{Min} \sum_l (n_l^{(1)} + p_l^{(1)})^p + \sum_s (n_s^{(2)} + p_s^{(2)})^p \\ + \sum_t (n_t^{(3)} + p_t^{(3)})^p \end{aligned}$$

Goals:

$$m_{ij} - m'_{ij} + n_l^{(1)} - p_l^{(1)} = 0$$

$$l = 1, 2, \dots, n(n-1)$$

$$m'_{ij} \times m'_{ji} - 1 + n_s^{(2)} - p_s^{(2)} = 0$$

$$l = 1, 2, \dots, \frac{n(n-1)}{2}$$

$$m'_{ij} \times m'_{jk} - m'_{ik} + n_t^{(3)} - p_t^{(3)} = 0$$

$$l = 1, 2, \dots, n(n-1)(n-2)$$

Auxiliary constraints:

$$L \leq m'_{ij} \leq U \quad \forall i, j$$

Nonnegativity constraints:

$$\mathbf{n} \geq \mathbf{0}, \mathbf{p} \geq \mathbf{0}$$

It can be observed that there are three blocks of goals corresponding to conditions of similarity, reciprocity, and consistency, respectively. Deviation variables in the first block have a very different range of values with respect to the deviation values associated with the other two blocks. Hence, it might be suitable to implement a normalization process in the achievement function.

The reader should note that for small values of metric p , the Archimedean GP model may provide solutions, which are too biased toward the achievement of one of the three blocks of conditions formulated earlier. As p increases, more importance is attached to the largest deviation. Thus, for $p = \infty$, the maximum disagreement is minimized. This type of analysis can be generalized, within a context of linearity, by resorting to the formulation of an extended GP model (see for details [10] and [12]).

Numerical Example

By applying the above procedure for metric 1 to the pairwise comparison matrix of the previous section, the following improved matrix was obtained:

$$\begin{pmatrix} 1.00 & 5.00 & 3.33 & 1.67 \\ 0.20 & 1.00 & 0.67 & 0.33 \\ 0.30 & 1.50 & 1.00 & 0.50 \\ 0.60 & 3.00 & 2.00 & 1.00 \end{pmatrix}$$

From this matrix, by applying the GP procedure proposed earlier, the following vector $\mathbf{W}$ of preferential weights was obtained:

$$w_1 = 0.476, w_2 = 0.095, w_3 = 0.145, w_4 = 0.286$$

For this solution, $\theta = 0.0022$ and $\theta' = 5.01$; therefore,

$$\text{IC} = [1 - (0.002/5.01)] \times 100 = 99.95\%$$

which improves the consistency of matrix M' with respect to the initial matrix M .

THE GROUP DECISION-MAKING PROBLEM

The purpose of this section is to provide some ideas on how to extend the above analysis to a context where there is a finite number r of DM, each one providing a pairwise comparison matrix. Depending on where the group wants to reach the consensus, in the final priority weights or in the initial pairwise comparison information, we can foresee two different aggregation problems.

- (a) Individual priority weights are computed and combined in a consensus vector of preferential weights [13, 14].
- (b) A consensus pairwise comparison is computed and a priority weight is obtained [15]. This is the scenario that we have adopted in this section.

In this context, we are concerned with the computation of a consensus pairwise comparison matrix M^C that differs from individual

matrices $M^1, M^2, \dots, M^r$ “as little as possible.”

In order to make operational the assertion “as little as possible,” we have again resorted to a family of distance functions based on the generic metric p , which leads to the following optimization problem:

$$\begin{aligned} \text{Min } & \sum_{t=1}^r \sum_{i=1}^n \sum_{\substack{j=1 \\ j \neq i}}^n |m_{ij}^{(t)} - m_{ij}^C|^p \\ & \text{s.t.} \\ & L \leq m_{ij}^C \leq U \quad i, j \in \{1, \dots, n\} \end{aligned}$$

where $m_{ij}^{(t)}$ are the elements of matrix M^t ($t = 1, \dots, r$) and m_{ij}^C are the elements of the consensus matrix M^C sought. The constraint set must establish, as usual, some scale conditions.

Again the nonsmooth character of the above objective function makes its optimization extremely difficult. However, it is once more quite simple to transform the above model into the following Archimedean GP formulation [12]:

Achievement function:

$$\text{Min } \sum_{t=1}^r \sum_{i=1}^n \sum_{\substack{j=1 \\ j \neq i}}^n (n_{ij}^t + p_{ij}^t)^p$$

Goals:

$$m_{ij}^C - m_{ij}^{(t)} + n_{ij}^t - p_{ij}^t = 0$$

$$i, j \in \{1, \dots, n\} \quad t \in \{1, \dots, r\}$$

Constraints:

$$L \leq m_{ij}^C \leq U \quad i, j \in \{1, \dots, n\}$$

$$\mathbf{n} \geq \mathbf{0}, \mathbf{p} \geq \mathbf{0}$$

Again the value of metric p attached to the objective function might have a strong influence in obtaining a good solution from the point of view of the average (small values of p) or a good solution from the point of view of the DM with views that are more displaced with respect to the consensus obtained (large values of p). Once more, the analysis can be generalized in a linear context by the formulation of an extended GP model (see for details [11, 15]).

Numerical Example

Let us illustrate how the theory presented in this section works with the help of a simple example. Thus, let us assume that we have four DMs with the following pairwise comparison matrices over four objects, using Saaty's scale:

$$M^1 \equiv \begin{bmatrix} 1 & 1/5 & 5 & 3 \\ 3 & 1 & 1/7 & 1/3 \\ 1/5 & 7 & 1 & 1/3 \\ 1/3 & 3 & 3 & 1 \end{bmatrix}$$

$$M^2 \equiv \begin{bmatrix} 1 & 3 & 1/3 & 1/3 \\ 1/3 & 1 & 1 & 5 \\ 3 & 1 & 1 & 7 \\ 5 & 1/5 & 1/5 & 1 \end{bmatrix}$$

$$M^3 \equiv \begin{bmatrix} 1 & 1 & 1/2 & 7 \\ 1 & 1 & 1/4 & 5 \\ 2 & 4 & 1 & 8 \\ 1/5 & 1/5 & 1/8 & 1 \end{bmatrix}$$

$$M^4 \equiv \begin{bmatrix} 1 & 7 & 7 & 3 \\ 5 & 1 & 1 & 1/5 \\ 1/7 & 1 & 1 & 1/5 \\ 1/3 & 5 & 5 & 1 \end{bmatrix}$$

By applying the above model to the four matrices, and by resorting to metric $p = 1$, the resulting consensus pairwise comparison matrix M^C is the following one:

$$M^C \equiv \begin{pmatrix} 1 & 2.11 & 4.43 & 3 \\ 1 & 1 & 1 & 0.33 \\ 2 & 1 & 1 & 7 \\ 0.33 & 3 & 0.20 & 1 \end{pmatrix}$$

It should be noted that the problem of inconsistencies analyzed in the previous section can be transferred to a group decision-making context in two different ways:

- (a) Analyzing individual pc matrices, M^1 , M^2 , . . . , M^r .
- (b) Analyzing the final consensus matrix M^C .

CONCLUSIONS

Pairwise comparisons leading to pairwise comparison matrices has become, in the last few years, a powerful multicriteria procedure, in order to obtain robust information from a single DM or a group of DMs. In this way, this procedure is a basic ingredient of several interactive multicriteria methods with many applications reported in the literature.

The success of this approach lies in its simplicity, which is close to common sense: “when it is difficult to provide preferential information about a large set of objects, then it is advisable to take only two parts at a time.”

Moreover, the derivation of a vector of preferential weights from a pairwise comparison matrix is relatively easy from a computational point of view. Thus, according to the rationality properties underlying the pairwise comparison matrix, there are different computational procedures (maximum eigenvalue, different GP formulations, etc.) that can be applied.

It is interesting to note that the gap between descriptive and normative models, which is a controversial topic in the decision-making literature, can be compromised within a pairwise comparison context without excessive computational difficulties. Finally, the extension of the pairwise comparison analysis from a single DM to a group decision-making context is a relatively straightforward task, leading to models easy to be computed.

ANALYTIC MODELING OF INSURGENCIES

MOSHE KRESS
Naval Postgraduate School,
Monterey, California, USA

INTRODUCTION

Combat modeling is one of the oldest areas of operations research, dating back to the Kriegsspiels—board war-games developed in the early nineteenth century for training, planning, and testing military operations in the Prussian Army. The ground-breaking work of Lanchester in 1916 [1] marks the beginning of formal models of conflicts, where mathematical formulas and, later on, computer simulations replace board games and sand tables. From WWII until a decade ago combat models have mostly been focused on the physical aspect of conflicts. These models have been typically applied to regular force-on-force engagements, where adversary armies, navies and air forces engage in, so-called, kinetic actions that comprise fire, maneuver, and attrition.

Insurgencies are not new either; they date as far back as the Jewish revolt against the Seleucid Empire in the second century BC. Since then, insurgencies have been prevalent throughout history. While fighting the Japanese Imperial Army occupying China, Mao Tse-tung was one of the first to offer a conceptual “model” of insurgencies in 1937 [2]. He described the insurgents as “fish” that must swim in the population’s “sea” to survive and prevail. More recent and formal models of insurgencies include Deitchman’s Guerrilla Warfare model [3], which is a Lanchester-based mathematical model (see more details about this model later on), and McCormick’s Magic Diamond model [4], which is a conceptual model that identifies the players in an insurgency and specifies the interrelationships among them. However, it is only since the early 2000s,

following major insurgencies in Colombia, Iraq, Afghanistan, Libya, and elsewhere in the Middle East, that operations-oriented modeling of these armed conflicts has become prevalent. In particular, during the Iraq and Afghanistan wars operations-research analysts were deployed with combat units to collect and analyze data. They also utilized reach-back support from operations research analysts in the United States for developing decision support models, for both combat tactics against the insurgents and information operations aimed at gaining the support of the local population [5].

Insurgencies are different than regular force-on-force engagements. The two adversaries in an insurgency are *government* organized forces on one side, and, on the other side, loosely organized nonstate actors, henceforth called *insurgents*, such as violent demonstrators, armed rebels, and terrorists. While there are some differences between *counterinsurgency* and *counterterrorism* operations—mostly in terms of scale of operations and countermeasures (see, e.g., [6])—in some places in the following, the two terms may be used interchangeably.

In one-on-one situations, the nonstate actors—the insurgents—are no match to the state-controlled government forces, who are significantly larger, better equipped, and better trained. To avoid eradication, the insurgents must reduce their signature as targets, and this elusiveness is attained by blending in with the civilian population among which the insurgents operate. The insurgents use relatively simple, yet lethal, weapons such as small arms, improvised explosive devices, and suicide bombs.

The asymmetry described earlier is one significant characteristic of insurgencies. The second characteristic is the active role played by civilians who provide insurgents, either willingly or as a result of coercion, hiding places, shelters, logistical support, and most importantly—information and recruits. Civilians play other roles too: They may provide information (intelligence) to

the government forces regarding insurgents' activities and whereabouts, they consume social and economic resources that are provided either by the insurgents or the government, and they are possible targets to violent actions by both sides (see e.g., the conflict in Syria that started in 2011). All these characteristics make civilians a key component in insurgency modeling, which is absent in legacy armed-conflict models. In particular, models from behavioral science, sociology, political science, and economics play a major role in insurgency modeling.

There are several ways to model insurgencies. Probably, the most popular models are detailed (e.g., agent-based) simulations that represent both physical and cognitive interrelations among stakeholders in such conflicts. Some examples of simulation models are mentioned later on. Another possible modeling approach is system dynamics [7]. A "softer" side of insurgency analysis—by means of political science, sociology, and behavioral science—is embodied in the works of Killcullen [8], which has been influential in planning counterinsurgency operations in Iraq and Afghanistan. Another important political and economic analysis of an insurgency is reported in [9].

In this article, however, we focus on OR analytic modeling based on formal methodologies such as differential equations, utility theory, game theory, and probability models. Besides their elegance, the conceptual simplicity of these models provides transparency, facilitates a clear description of cause-and-effect relations, and thus offers strategic insights regarding insurgency situations. Because of these features, some of the models presented later have been briefed to top leadership in the US Army.

Following a general discussion on analytic modeling of insurgencies presented in the next section, we describe three families of models addressing three major issues: (i) *Eyes and Ears*: the impact of information, intelligence, and situational awareness on the conduct of counterinsurgency operations, (ii) *Hearts and Minds*: the effect of civilians' behavior and attitude toward the insurgents and the government, and (iii) *Bullets and*

Fire: the "kinetics" of insurgencies that represents the physical attrition in this type of conflicts. The three families are obviously related—for example, informational models may have some attrition and behavioral components. Thus, the classification mentioned—information, behavior, and attrition—only serves for highlighting the main thrust of the models included in each corresponding section.

THE BIG PICTURE

The three major players in an insurgency are the two adversaries—the government forces and the insurgents—and the civilian population, which is caught in the middle. A fourth player is the international community [4, 10] who may (e.g., Libya, 2011) or may not (e.g., Syria, 2011–2014) be actively involved in the conflict. Because international forces, if they get actively involved in the insurgency, typically side with either the government (e.g., Afghanistan) or the insurgents (e.g., Libya), we will focus only on the three main players, as shown in Fig. 1.

The government and the insurgents are engaged in an armed conflict (the "Combat" link in Fig. 1) governed by violent actions and mutual attrition. The civilian population is divided into three groups: *supporters* of the government, *supporters* of the insurgents henceforth called *contrarians* and those who maintain neutrality. The government and the insurgents, while trying to gain the support of the population, provide social benefits such as healthcare and education; however, they may also impose some requirements such as dress codes, taxes, and draft. The insurgents also use aimed violence against civilians to coerce them to collaborate and deter them from supporting the government. These actions, combined with observations on the state of the armed-conflict between the insurgents and the government forces, lead to shifts in civilians' behavior regarding their support to the two sides. Contrarians support the insurgents by providing hiding places, recruits, logistics support, and information, while government supporters mostly provide information, in the form of human intelligence (HUMINT), to government forces.

Figure 1. The stakeholders in an insurgency.

As mentioned earlier, the blue block corresponding to government forces in Fig. 1 may contain several stakeholders such as regular government army, police forces, and international forces supporting the government. The red block corresponding to the insurgents may also comprise nonhomogeneous forces in the form of a number of competing tribal or sectarian militias who may also fight each other to gain control of the insurgency (e.g., Syria 2013–2014).

There were several attempts to develop analytic insights regarding the observed evolution of insurgencies. Bohorquez *et al.* [11] examine the patterns of violence in insurgencies and terror events and identify a common pattern regarding the size distribution of such events and their timing. Their dynamic model explaining this pattern is based on the notion of coalescence and fragmentation of insurgents or terror organizations, thus producing ecology of groups. A more recent paper [12] reveals a dynamical pattern of fatal insurgency attacks. This pattern, which is manifested in a power law, identifies possible escalation scenarios of such attacks. The authors establish a new metric for understanding the momentum of these attacks and the effectiveness of COIN actions—a metric that appears to be stable across multiple conflicts and at different scales.

EYES AND EARS

Situational awareness regarding the battle-field, generated by a steady, relevant, and reliable stream of intelligence reports, is an important factor in any armed conflict. In order to effectively deploy and operate its weapons and other combat assets, a military force needs to know the deployment, capabilities, plans, and intentions of its adversary, as well as details regarding the combat environment. Situational awareness becomes even more critical in counterinsurgency operations because of the two aforementioned characteristics: asymmetry and the significant active role of civilians. First, the asymmetry is manifested in elusive, well-hidden insurgents, diffused among civilians and thus reducing their signature as targets. This elusiveness requires extra effort by the government forces—mostly by acquiring intelligence from human sources—to locate and effectively engage the insurgents. Second, the impact of civilians on the evolution of an insurgency necessitates social, cultural, and behavioral intelligence about the population’s attitude, mood, and sentiments. This type of intelligence is typically absent in legacy force-on-force conflicts (see also Section HEARTS AND MINDS).

Generalized Deitchman Model

The first to capture the asymmetry feature in a Lanchesterian setting was Deitchman [3] in his Guerrilla Warfare model, which is a pair of differential equations. If $G(t)$ and $I(t)$ are the sizes of the government forces and the insurgents at time t , respectively, and P is the size of the civilian population, then Deitchman's model states that

$$\begin{aligned} G'(t) &= -\alpha I(t) \\ I'(t) &= -\gamma G(t) \frac{I(t)}{P} \end{aligned}$$

where α, γ are attrition coefficients and the signature of the insurgents—their proportion in the population—is represented by $\frac{I(t)}{P}$. The larger the population, among which the insurgents are diffused, the smaller is the insurgents' signature and thus the smaller the effectiveness of the government forces in fighting the insurgents. Deitchman's model was extended in [13–15]. Absent accurate situational awareness, that is, information regarding the whereabouts of the insurgency targets, not only might the guerrillas be able to continue their insurgency actions unhindered, but also the collateral damage caused to civilians from poor targeting by the government forces may generate an adverse response against the government, thus creating popular support for the insurgents [16]. This popular support may translate into new cadres of recruits to the insurgency ranks [17]. This dynamics of two-sided attrition, collateral casualties among civilians, recruitment to the insurgency, and reinforcement to the government forces, is captured by a pair of differential equations in [14]. The imperfect situational awareness, which results in collateral casualties, turns out to be crucial. Analyzing the differential equations model results in some operational insights. While perfect targeting would eradicate the insurgents in no time, it is shown that, under reasonable assumptions, the government forces can never do that if the situational awareness is imperfect. The best the government forces can hope for is containing the insurgency at some manageable size, a result that has been confirmed empirically in recent insurgencies

(e.g., Afghanistan and Syria). Moreover, it is shown that there may be two steady-state containment situations. One stalemate scenario involves relatively low level of violent activity by the government forces. However, this stalemate is fragile from the government point of view; small changes in the balance of forces could lead to quick government demise. The other steady-state containment scenario involves high level of violent activity and is more stable. In any case, the only alternative, which is the worse-case scenario for the government, is when the latter actually loses, as was the case in Libya, Tunisia, and Yemen in 2011 (aka “Arab Spring”).

Searching for Insurgents

Optimizing the search for hiding insurgents could be modeled as a *whereabouts search* problem [18]. The objective here is to detect, as fast as possible, an insurgents' cell that is hidden in one out of n possible locations observed by an imperfect sensor. The cost of searching a location is c , and the intelligence obtained from this search may be false negative (the searcher failed to detect an insurgents' cell) with probability $1 - p$, false positive (the searcher erroneously identifies a location as an insurgents' cell), with probability q . An indication by the sensor that a certain location is an insurgents' cell, may be *correct*—insurgents are indeed hiding in that location—or *wrong*—the location is void of insurgents. Following such an indication (correct or wrong), a combat team is sent out with the objective to capture the insurgents in the indicated location. The operational costs of such actions are C_P and C_W , for *correct* and *wrong* scenarios, respectively. In case the indication is wrong, the cost may be collateral damage and lost of time and effort. It is shown in [19] that the optimal search sequence of the sensor follows a greedy policy that only depends on the prior location probabilities and the values of $\frac{p}{C_P + qC_W}$ in the various locations.

Balancing Between Intelligence Collection and Analysis

Collecting, processing, and analyzing intelligence for obtaining a current and reliable

situational awareness is a complex task that requires considerable resources. In particular, it is crucially important to balance off between the collection effort—gathering information and data from an assortment of sources—and the analysis effort—analyzing the collected information and producing useful operational knowledge. In a model that addresses this issue [20], using game-theoretic arguments in a queuing setting, assuming two types of traffic—light and heavy, the authors identify equilibria under various operational scenarios. They conclude that contrary to current practices in the counterterrorism intelligence community, more should be invested in analysis so as to reduce the size of the queue of intelligence input.

HEARTS AND MINDS

First coined by the British in Malaya during the early 1950s of the last century, and later on used in Vietnam (1960s) and more recently in Iraq and Afghanistan, “winning hearts and minds” is an operational concept that aims at swaying public support toward one side in the conflict. Because public opinion plays a major role in shaping the way an insurgency evolves, both sides—the government and the insurgents—take actions to win the support of the people. Which actions are effective? How do these actions interact? What is the end-effect of these actions? These types of questions have been addressed mostly in simulations [21], such as agent-based simulations [22, 23]. Various empirical approaches for addressing these questions have been reported in the political science literature, for example, [9, 24]. Modeling public behavior takes into account the difference between the *attitude* of an individual (his “heart”) and his *behavior* (his “mind”). For example, a person who fundamentally opposes the insurgents in his heart (attitude) may express latent or even active support to the insurgents in his mind (behavior) based on pragmatic considerations. The terms attitude and behavior used here are related, respectively, to the terms “private preference” and “public preference” used in [25]. While it may be hard to change the attitude of people—their fundamental

beliefs and values that have been shaped over centuries of cultural evolution—it may be possible to affect their manifested behavior, which is influenced by interests and utilities.

Carrots and Sticks

An analytic model that captures the aforementioned utilitarian aspect is presented in [26]. The situation modeled therein is as follows: a certain region is under the control of the insurgents who act there quite freely. Civilians in that region react to these actions based on their perception regarding the capabilities and intentions of the government, had it been in control instead of the insurgents, to improve or worsen their welfare. The insurgents execute two types of actions: (i) violent actions, aimed to coerce potential supporters of the government, which are only targeted at such suspected civilians (y), and (ii) nonviolent supportive economic and social actions aimed at gaining the population support (x). The dilemma of the insurgents is how to balance these two types of actions—the “sticks” y and the “carrots” x . A dynamic utility-based model is developed in [26] in which the state variables are the fractions of contrarians (supporters of the insurgency) (C), latent supporters of the government (L) and active supporters of the government (A) in the population. The model is parameterized by the activity levels of the insurgents (x, y) for both nonviolent and violent actions, which are assumed to be bounded by the available resources to the insurgents, as depicted in Fig. 3. It is shown that the model converges into equilibrium, and the main insight is that tipping points may occur, where small changes in the aforementioned balance between insurgents’ violent (y) and nonviolent (x) actions can drastically change the size of active supporters who help the government. See Fig. 2.

The government should be aware of potential tipping points that lead to the elimination of most active supporters and attempt to avoid situations that lead to them.

Civilians’ Reaction to Violence

How civilians remember and react to violent actions by both sides—the insurgents

Figure 2. Cascading effects of insurgency's actions.

and the government—is modeled in [27]. Arguably, the exposure to violence affects the people's sense of security and is a major factor in shaping their allegiance to one side or another. *Ceteris Paribus*, people will support the side that provides a better sense of security [17, 28]. A key question is, how do people remember violence; is it the first exposure to violence that shapes their behavior or the last such encounter? The dynamic differential equations model in [27] takes into account the violence intensity ratio of the government and the insurgents, the effectiveness of coercion by the insurgents, the targeting accuracy (see Section “Eyes and Ears”), and the way civilians remember and respond to violence. The main conclusions of the analysis are (i) excess violence and poor targeting accuracy may lead to situations where civilians' support for a certain side will vanish; (ii) the government should not be discouraged by an initial small level of popular support, because there are situations where this would actually play to its advantage if the insurgents are very violent and have poor situational awareness; (iii) the effect of the initial distribution of opinions (support or opposition to a certain side) among civilians on the outcome of the insurgency depends on the way people remember and respond to violent experiences. For some responses the outcome is insensitive to this initial distribution.

BULLETS AND FIRE

As observed by Deitchman [3] and others (see Section “Eyes and Ears”) counterinsurgency

is essentially a contest of attrition that lends itself to classical combat modeling [29, 30].

Confronting Entrenched Insurgents

Similarly to Deitchman [3], Kaplan *et al.* [31] used modified Lanchester models to study the force allocation problem of both the government and the insurgents and, using a sequential force allocation game between the two sides, obtain an equilibrium. It is shown that the insurgents' optimal strategy depends on the government level of situational awareness; when the government has perfect intelligence in equilibrium, the insurgents concentrate their force in a single stronghold that the government either attacks or leaves unengaged, depending on the resulting casualty count. Otherwise, under reasonable assumptions regarding the government's behavior and intelligence capabilities, it is optimal for the insurgents to “spread out” in a way that maximizes the number of soldiers required to win all battles. This type of behavior was observed during the 2006 war against the Hezbollah in Lebanon, and the 2014 war against the Hamas in the Gaza Strip. On the other hand, for a given allocation of insurgents across strongholds, it is shown that an optimal selection of insurgents' strongholds to attack can be (approximately) accomplished with a simple knapsack rule that depends on the force size of the insurgents in a certain stronghold, the one-on-one fire-exchange relative strength, and the level of situational awareness.

Controlling Territories

Also based on a Lanchester setting, a model that accounts for the split between territorial regions loyal to the government and regions favoring the insurgents is described in [32]. Let B denote the government forces and R the insurgents. Also, the fraction of regions inhabited by government supporters is S and the fraction of insurgents' supporters country is C , $S + C = 1$ —see Fig. 3. SB and CR indicate the fraction of regions that are liberated. That is, SB is the proportion of the S regions approvingly controlled by the government, and CR is the proportion of the C regions approvingly controlled by the insurgents. Similarly, SR and CB indicate subjugated regions—regions coercively controlled by the other side. Solid lines in Fig. indicate changes in control due to liberation, while dashed lines indicate subjugation. Regions do not change allegiances even under occupation, and each side can exert military force, to liberate or subjugate, only out of regions that support that side. It is shown that contrary to classical Lanchesterian insights regarding traditional force-on-force engagements, the outcome of an insurgency is independent of the initial force sizes; it will only depend on the fraction of regions supporting each side and the combat effectiveness of each side. Moreover, unlike legacy force-on-force situations, counterinsurgency allows for stalemates (see also Section “Eyes and Ears”). Very often it is hard to avoid stalemate without foreign support. The foreign support in Libya in 2011 led to a victory by the insurgents, while lack of such support in Syria has resulted in an ongoing stalemate where some regions are controlled by the Assad forces and others are controlled by the insurgents. The model's predictions have been consistent with the recently observed situations (2010–2014) in Afghanistan, Libya and Syria.

Tactical Issues

A common threat in insurgencies is roadside attacks by improvised explosive devices [33]. A model addressing this problem is given in [34]. On the basis of collected data on attacks against coalition forces in Iraq, the paper presents a stochastic, game-theoretic, model

Figure 3. Schematic dynamics of the territorial model.

for optimally allocating clearing devices by the Coalition forces on a network of roads. The insurgents are strategic; they observe the Coalition forces' actions and they react to them. A related problem is the optimal interaction between a single military convoy of government forces and a single route-clearing team operating on a single roadway [35].

Another common threat by insurgencies—mostly used as terrorizing and coercing means against civilians—is suicide bombing. A person acts as a live bomb, killing and harming other people while killing himself or herself. The physics of this type of attack is studied in [36], where the effect of crowd blocking emerges as a significant factor in estimating the number of casualties. Mitigation tactics for this type of attack are examined, using probability models, in [37]. It is shown that even under best-case assumptions regarding the effectiveness and timeliness of widespread deployment of detection sensors against potential attackers, the expected number of casualties will not be significantly reduced compared to no detection. Thus, suicide-bomber-detector schemes will not likely to prove effective in protecting civilian populations from random pedestrian suicide-bomber attacks. The effort should be focused in prevention, rather than mitigation. In other words—invest in intelligence.

SUMMARY

Insurgencies are different than regular armed conflicts in the way, they are physically manifested and the role civilians play in them. These differences are reflected in mathematical models that attempt to study,

analyze, and understand this type of confrontations. From purely attritional focused models that characterize legacy force-on-force abstractions, insurgency models move to behavioral, social, political, and economic domains. The main challenges in insurgency modeling lie in these domains and are mostly associated with data collection and interpretation. Insurgency modeling will experience a huge leap in application and relevance once effective and reliable data-collection methods will be in place for monitoring public mood, sentiments, and behavior doing such armed conflicts. The advent and proliferation of observable social networks may give this capability a significant boost.

Thanks to the abundant consumer transaction data collected and ample cheap computing power, retailers have begun to develop and employ analytical methods as decision support tools for their various operation and management tasks. They hire either analytically trained individuals or specialized retailing consulting firms to develop their proprietary software for that purpose. In either case, they turn to the wealth of academic models for ideas of developing their own practical models. Generally, however, there are differences between the academic and practical models. Sometimes, academic models are overly simplified such that a lot of challenging issues are left unsolved; sometimes, academic models are too complicated such that it would be too hard or costly to implement them in practice. In this article, we focus on two types of commonly used analytics in retail practice, forecasting, and optimization, and present two models, motivated by academic research, that are in production use or development in retail business settings.

FORECASTING

Forecasting is one of the earliest and most common analytics carried out in retail practice. It provides vital input to almost all of the other analytics in retail functions such as marketing, merchandising, and operation, and for management tasks such as planning, budgeting, and controlling. Its methods can be roughly divided into judgmental and statistical methods. Judgmental methods

prevailed in the early days of retailing, when there were only limited products as well as scarce recorded data. These methods are subjective and are nearly pure art with little science. They are still useful tools for forecasting sales in some cases such as innovative products (e.g., the iPad) or fashion goods, which have no direct relevant historical sales. And, expert judgment can convey valuable knowledge and experience, which can be used to improve the performance of statistical methods [1]. But, statistical methods are the basic tools for modern forecasting system in retail. They make use of the large-scale data collected through an IT system. They are objective, scientific, and can be automated. Statistical forecasting methods can be further divided into extrapolation and causal methods. Techniques of extrapolation methods include the simpler moving average and exponential smoothing family, and the more sophisticated Box–Jenkins approach [2]. They use only the time series data of the forecasting subject. Franses [3] discusses the application of extrapolation methods for business and economic forecasting. Causal methods, on the other hand, build statistical models using both the data of the forecasting subject and potential causal factors. Some causal factors, such as prices, promotions, advertising, are under the control of management, and the others, such as competitor prices, weather, changes in competitive landscape, and market demographics are not. Despite the simplicity of judgmental and extrapolation methods in retail practice, the more complicated causal forecasting methods play an important role in the retail industry and are the focus of this article.

In what follows, we use a promotion forecasting example to illustrate these causal forecasting methods. This example employs a multiple linear regression model for forecasting, which is most often used in causal methods. We highlight some of the issues commonly encountered in retail forecasting using causal statistical methods, and an innovative solution for one of them.

Promotion Forecasting

An important class of decisions made by retailers is related to planning a promotional strategy. These decisions include which products to promote; what promotional prices to offer; how to communicate the promotional offers to customers, either via various media channels or in-store; and how to execute the promotions. Promotion decisions may be made on a chain-wide basis, or may be tailored to specific markets, store types, and stores. These decisions can be informed and supported by promotion forecasting, which aims to forecast the magnitude of the impact of a particular promotion on both the promoted products, and products complementary or substitute to the promoted ones. Promotions forecasting methods embedded in decision support have been shown to provide substantial increments in revenue and gross profit. The benefits accrue in three areas. First, retailers can make more informed decisions about promotional plans, including items, timing, and targets, subject to a given level of support from vendors. By basing such decisions on better understanding of the profitability of a promotion, the retailer can lessen the risk of unprofitable promotions, and make the most effective use of promotional “budgets.” Second, the retailer is able to provide higher service levels on the promoted items by improving the forecast accuracy, which translates into fewer lost sales and greater revenue. Finally, better forecasts for promotional items can also improve inventory management, and hence reduce the ordering and holding costs.

The forecasting method described in this section features an integrated demand model, which captures the sales effects of various promotional features, both in the item being promoted and other related items. Ordinary least square estimates of these effects, calibrated on historical sales and ancillary data, are used first in a promotional planning tool to support choices on promotional activities, and, once plans are finalized, in the inventory management tools to plan inventory for items influenced by the planned promotions.

Forecast Constituents

Secular Effects. Secular effects are predictable effects of phenomena that are time based. Although predicting these effects is not the chief goal of the promotion forecasting model, they are important for two reasons. First, in order to estimate the effects of promotional features, it is necessary to “untangle” the effects of the promotion on sales from the effects of these other phenomena. Second, when the retailer is considering the specific details of a promotion under consideration, the ultimate effects of the promotion on sales often depend on the level of sales when the promotion is absent, which in turn depends on these secular effects. Our model incorporates three secular effects: demand level, seasonal effects, and holiday effects; it could be expanded to include a trend effect as well. The demand level is interpreted as the average (or deseasonalized) sales under a regular pricing regime. The seasonal effects indicate how sales vary over a year. They are captured at the weekly level in the promotion forecasting model, which works well in practice. We include holiday effects in addition to the weekly seasonal effects because the same holiday may not happen at the same week each year.

Own Effects. Own promotional effects are the influence of the promotional features on the sales of the item being promoted. Any particular promotion is characterized by a vector of promotional features. These features can be categorized into four classes: the discount or temporary price reduction; the mechanism by which the offer is extended (e.g., straight discount, “buy one, get one free”); the way in which the offer is communicated or promoted in the store (e.g., on shelf and aisle end cap); and the way in which the offer is communicated outside the store (e.g., circular front page, brand advertising). For example, a particular promotion may be a 50% discount on shelf promotion with “buy one, get one free” mechanism and circular front page advertising. To forecast the own effects for such a promotion, we just need to combine

the effects of its feature vector. These effects are combined multiplicatively.

Own effects of a promotion can either be on sales that occur contemporaneously with the promotion or on sales before or after the promotion. The effect on sales before or after the promotion is sometimes referred to as *retiming*, *self-cannibalization*, or *pantry loading*. It occurs when consumers either defer purchases until the promotion is in effect, if it can be anticipated, or when consumers stock up on the item during the promotion and purchase less afterwards. Our model incorporates both the contemporaneous own effects and the retiming effects.

Cross-Effects. Cross-effects are the influence of the promotion on items other than the one being promoted. Cross-effects can happen either for complement or substitute items. Items that are substitutes for the promoted item may experience a decrease in sales. These are sometimes referred to as promotional *victims* (e.g., different pack sizes of the same item and other brands of the same item). Other items, which are complements to the promoted item, may experience an increase in sales. These are sometimes referred to as *halo* items (e.g., snacks, when beer is promoted and accessories, when furniture is promoted).

Another type of cross-effects arises when a promotion is undertaken to stimulate traffic in the whole store, from which sales of many items may benefit. Some of these items may be neither complement nor substitute to the promoted items. The promoted item is sometimes referred to as a *loss leader* or a *traffic-driver*. A typical example of a loss leader in grocery is milk. Retailers sometimes reduce the price of milk less than its cost to attract shoppers to their stores. Our model incorporates both types of cross-effects.

Full Model. We model the effects in the promotion forecast multiplicatively. For seasonal and holiday effects, this is merely a choice of convenience, and is consistent with most other work in the area of retail forecasting. For the own- and cross-effects, the multiplicative formulation is motivated by the fact that the own- and cross-effects clearly

depend on the baseline sales of the promoted item and related items. Multiplicative models automatically capture this kind of dependence while additive models cannot.

The full forecast model for item i is given by

$$\begin{aligned} \text{Sales}_{i,t} = & \text{Level}_i \times \text{SeasonalEffects}_{i,t} \\ & \times \text{HolidayEffects}_{i,t} \\ & \times \prod_{k=1}^K \beta_{i,k}^{\text{own}} \times \text{PromoFactor}_{k,t} \\ & \times \prod_{l=1}^L \prod_{j=1}^J \beta_{i,l,j}^{\text{cross}} \text{RelatedItemPromoFactor}_{l,j,t}, \end{aligned}$$

where k indexes the factors representing the promotional features for item i , which are being offered at time t , and β^{own} are the own effects for each of the K factors; l indexes the items being promoted with cross-effects on item i ; j indexes the attributes of each of the L other items being promoted at time t and β^{cross} are the cross-effects for each of the J factors.

Implementing such a model requires making choices about inclusion of effects and the way in which effects are modeled. We discuss some of these choices with an example.

In this promotion planning example, the promotion under consideration is for a branded grocery product, peanut butter. The features of the promotion are a “buy one, get a second for half price” offer and a large display at an end of an aisle. For simplicity we consider only two related items, a larger package of the same brand and a similar size package of a house brand. The promotion is planned to run for two weeks, corresponding to week indices 13 and 14. The estimated effects are presented in Table 1.

The first column displays the own effects. The demand level and seasonal effects provide the baseline (i.e., nonpromoted) forecasts. This promotion offers an effective discount of 25%; we have an estimated effect (demand lift) of 1.32 for discounts in the range of 20–25%. An alternative way to model this effect is to treat the discount as a continuous variable and the effect as price elasticity. An advantage of the discrete discount buckets

Table 1. Promotions Forecasting Effects

Promotion Forecast Effects	Premium Brand 14 oz	Premium Brand 32 oz	House Brand 15 oz
Demand level	66	27.5	83.7
Seasonal effect, week 13	1.16	1.16	1.16
Seasonal effect, week 14	1.16	1.16	1.16
Seasonal effect, week 15	1.14	1.14	1.14
20–25% discount	1.32		
Buy one, get one half off	1.04		
Major end aisle display	1.23		
Retiming effect	0.78		
Cross-effects of 14 oz premium brand promo with display		0.41	0.68

is that it is nonparametric, offering a more flexible way to model the discount effects. The promotional mechanism “buy one, get one half off” is estimated to have a lift of 1.04. The fact that this is greater than 1.0 indicates that this form of the offer is more effective than simply offering a 25% discount. The way by which the promotion is communicated in the store, using a large end cap display, is estimated to have a lift effect of 1.23. Finally, we have a retiming effect of 0.78 on the sales of the promoted peanut butter the following week.

For many retailers, there can be a large set of promotional mechanisms and in-store communications, as well as promotional advertising possibilities. For the purpose of modeling and estimating the effects, these can be consolidated into a smaller number of alternatives of each of the three main categories.

The second and third columns in Table 1 display the baseline forecast effects and the cross promotional effects for the other two items in the subcategory. The cross-effects predict the sales impact of a promotion on the 14 oz Premium brand, on each of these other two items, given that the promotion includes a display. In the present case, the 0.41 effect for the 32 oz Premium brand indicates a large reduction in sales volume, due to a high degree of substitutability across sizes of identical items. The effect on the sales of the like-sized House brand is less, indicating a lesser degree of substitutability with the promoted item.

As with the own effects, there are a variety of ways to model the cross-effects. In this

example, we strike a compromise between the simplest model, which reflects only the presence or absence of a promotion of a related item, and a much more complex model, which attempts to estimate the effects of all the various promotional attributes on the sales of the related item. Note also that, in this promotions planning example, there are no complementarity cross-effects.

Challenges

Data Preparation. The presented forecast model is based on information from the point-of-sales (POS) and the promotion planning and execution systems. Neither the POS nor the promotion execution systems were designed with a view toward supplying data to support a forecasting model and process, and thus the source data require inspection and cleansing prior to being used. The primary hygiene tasks are to ensure the plausibility of data values and consistency of data across systems. Once these checks are accomplished, the sales data are summed to weekly values, whose start and end dates correspond to the promotions calendar. These values are then further cleansed of outliers and are matched up to the historical promotion information, providing the essential ingredients to estimate the effects.

Typical Problem Sizes. In 2008, the average number of Stock Keeping Units (SKUs) carried in a typical US supermarket was 46,852 according to the Food Marketing Institute. The number of stores a large retail chain may have is in the order of thousands.

For example, Wal-Mart has more than 8000 retail stores under 53 different banners in 15 countries [4].

Promotion planning systems will typically support dozens to hundreds of different promotion features. Localization of promotional planning and execution of some large retailers can increase the large-size retail forecasting problem even further. For example, a grocery chain with approximately 1000 stores may have 25–30 different price zones in which there are different promotional effects to forecast. Although costs of computing are not much of a constraint, especially with the advent of cloud computing, the large size of the problem requires careful design of the automation of the estimation process, which can take many hours to execute. Further, with so many combinations of item, location, and period, the majority of historical data used to calibrate the model is sparse. Aggregation and pooling are strategies for facilitating estimate of the effects in the presence of sparsity.

Aggregation and Pooling. In forecasting problems amenable to the extrapolation or time series methods, sparsity is often addressed through aggregation and disaggregation methods [5,6]. In promotional forecasting models (and causal models, generally), aggregation is problematic, since SKUs which might be aggregated are likely to have histories with different promotion timing and features.

In causal forecasting models, pooling data for different items and different locations can improve the estimability and reliability of effect estimates. The challenge is to devise a means of defining pools or clusters of items that are homogeneous in the effects.

One approach to find item-level clusters is a two-stage method. We first assign each item an attribute vector. After that, we can group items together according to the assigned attribute vector by some clustering algorithm like K-means or hierarchical clustering. For example, Zotter *et al.* [5] used normalized store sales to group stores with similar seasonal effects. Products are often grouped according to certain physical or usage attributes, such as product category

or performance grade. The problem with this approach is that it is hard, *a priori*, to align the attribute vector with the regression effects across which we want to pool.

KMeans—GA Algorithm. An alternative approach not relying on these artificially assigned attribute vectors is cluster-wise linear regression. The basic idea of this modeling approach is to consider clustering and regression concurrently. In this way, the difficulty of aligning the attribute vector and the regression effects is bypassed.

We have developed a heuristic algorithm, termed *the KMeans-GA algorithm*, which is able to find clusters of similar items efficiently and effectively. This KMeans-GA algorithm hinges on the work by Maulik and Bandyopadhyay [7], where the authors embed a K-means procedure into the genetic algorithm framework for the standard clustering problem. Along the same line, our KMeans-GA algorithm also embeds a structure exploring K-means-like procedure into the genetic operations. For our cluster-wise linear regression problem, each cluster of items is encoded by a vector that stores the regression effects. These regression effects define similarity among items, according to which the K-means part assigns items to different clusters. The vector of regression effects is updated by running regression over new clusters generated through the K-means part. The genetic algorithm part performs genetic operations on the population of vectors of regression effects. The genetic operations include the standard selection, crossover, mutation, and elitism. We refer to Fig. 1 for a simple example that illustrates the KMeans-GA algorithm. In this example, each cluster i has the same regression model $y = \sum_{j=1}^3 x_j \beta_j^i$ with different estimates for the regression effects β_j^i 's, where the superscript i indicates cluster i . We divide the items into two clusters.

We tested our KMeans-GA algorithm on the promotion forecasting problem to find SKUs with similar seasonality patterns. We found that the heuristic approach performs very well; the difference in total sum of squared regression errors between our heuristic and optimal solutions is below

Figure 1. Illustration of the KMeans-GA algorithm. (a) Set of items to cluster; (b) random generation of n sets of clusters; (c) encoding of each set of clusters using corresponding regression effects; (d) selection of two chromosomes for genetic operations; (e) crossover in genetic operation; (f) generation of new set of clusters through K-means-like procedure; (g) update of coding for new chromosome.

2% in the test cases. In addition, the improvement of our KMeans-GA algorithm over the attribute-based two-stage method is significant; reductions in Sum-of-Squares Error (SSE) of greater than 30%. Finally, in a number of test cases, the procedure

revealed evidently better and more granular predictions about seasonal effects than the two-stage method. Figure 2 shows the seasonal effects estimated for a group of SKUs pooled on the basis of an attribute, the subcategory of the product. The only

K-means like procedure:

Item A is assigned to new cluster 1 if and only if

$$\sum_{k=1}^K (y_k - \beta_1^1 x_{k1} - \beta_2^1 x_{k2} - \beta_3^1 x_{k3})^2 \leq \sum_{k=1}^K (y_k - \beta_1^2 x_{k1} - \beta_2^2 x_{k2} - \beta_3^2 x_{k3})^2$$

Otherwise, Item A is assigned to new cluster 2.

Here, $(y_k, x_{k1}, x_{k2}, x_{k3})_{k=1}^K$ is the data for item A

(f)

(g)

Replace chromosome 1 with new chromosome 1 if the latter has larger fitness.

(h)

Figure 1. (Continued)

significant seasonal pattern was observed in weeks 51 and 52. For the same set of SKUs, the method revealed pools with appreciably different and more pronounced seasonal effects, as shown in Fig. 3. These seasonal patterns were confirmed by retail experts for the SKUs under study.

OPTIMIZATION

Optimization is not a commonly used tool in retailing as forecasting. Retailers are more comfortable making decisions by asking “what-if” questions than resorting to optimization models. The reason is the lack of the underlying intuition of an optimization model in the absence of technical background

and confidence. But thanks to recent collaborations between researchers in academia and some leading retailers, selected optimization models have made their headway into retail practice. Among them, assortment planning and price optimization models are the two prominent classes. Nevertheless, there are gaps between academic and industry models. Please refer to the section titled “Retail Applications” in this encyclopedia for academic models for assortment planning and price optimization. In what follows, we introduce a novel optimization model jointly optimizing price, assortment, and presentation (i.e shelf space) for a group of substitutable products. The model strikes a balance between complexity, relevance, and adoptability.

Figure 2. Seasonal pattern for an attribute-based cluster of approximately 350 SKUs.

Figure 3. Three distinct seasonal patterns revealed for same SKUs.

Optimizing Price, Assortment, and Presentation

In a typical retailer, macrolevel assortment decisions, for example, how much space to allocate to each category or department, are strategic decisions driven by considerations of the image or position of the chain, an appreciation of what items have been winners and losers, relationships with vendors, and the size and layout of the store. As a matter of operational practice, these macro-level assortment decisions either ignore heterogeneity in tastes and preferences across markets, or accommodate it coarsely by differentiating assortment plans by geographic store groups. More micro-level decisions are typically made by buyers or category managers and presentation decisions are typically undertaken by space planners, especially in grocery retailing. They have to decide, in each subcategory or finer categorization of items, precisely what size package of which brand and how many facings of each to display. These decisions are made on the basis of the particular display space available, visual appeal, negotiations with vendors, and received wisdom about

what has “worked” in the past. Finally, item-level pricing decisions are the responsibility, in some cases, of a pricing department, and, in other cases, by the merchants or category managers. For most retailers, these decisions are made based on judgment, informed of high-level policy rules governing markups, price image, and promotional positioning. In some more sophisticated retailers, analytic-based tools are used to support these decisions, sometimes including price optimization tools. The latter rely on models of demand which predict sales changes due to price changes, and may even include substitution and complementarity effects. But even these sophisticated price optimization models are insensitive to assortment and presentation decisions.

Studies of these assortment, pricing, and presentation decisions suggest that category profits may be improved by upward of 50% by independently optimizing these decisions, [8–12].

Demand Effects

Substitutable Item Groups and Price Effects. A “substitutable item group” (SIG), is a set

of candidate items to offer and present which are strong, but imperfect substitutes for each other. They would typically comprise items of the same brand in different packages and flavors, as well as comparable items in different brands. A typical grocery retailer, for example, will sell 30,000–50,000 items in 50–150 categories. Each category would comprise 15–100 SIGs. Thus, an SIG may comprise from as few as 2 to 20 or more items. In practice, on an average, there are 7–10 items per SIG.

We first model demand for the SIG as a whole, and then use a demand share model to obtain the demand for each individual item. Let M be the set of all items in the SIG and M^* be the subset of M comprising the items actually assorted. Quantity Q_{SIG} , the total demand of the entire SIG, is assumed to be responsive to $\mathbf{p} = (p_i)_{i \in M^*}$, the selling prices of the items offered:

$$Q_{\text{SIG}}(\mathbf{p}, M^*) = Q_{\text{SIG}}^r \left(\frac{p_{\text{SIG}}(\mathbf{p}, M^*)}{p_{\text{SIG}}^r(M^*)} \right)^{e_{\text{SIG}}}, \quad (1)$$

where Q_{SIG}^r is the reference sales for the SIG under the reference prices, e_{SIG} is the own-price elasticity of demand for the SIG, and p_{SIG} and p_{SIG}^r are the reference share-weighted selling prices and reference prices, respectively, of the items that are offered in the SIG. More specifically,

$$p_{\text{SIG}}(\mathbf{p}, M^*) = \sum_{i \in M^*} S_i^r p_i \Big/ \sum_{i \in M^*} S_i^r,$$

$$p_{\text{SIG}}^r(M^*) = \sum_{i \in M^*} S_i^r p_i^r \Big/ \sum_{i \in M^*} S_i^r,$$

where S_i^r is the demand share for item i under the reference prices p_i^r .

To model the demand shares assorted for individual items, we include an “outside” good to account for no-purchase decisions. Both the own items’ shares and the outside good’s shares respond to their prices:

$$ST(\mathbf{p}, M^*) = \sum_{i \in M^*} \left(S_i^r \left(\frac{p_i}{p_i^r} \right)^{e_i} \right)$$

$$+ S_{\text{OG}}^r \left(\frac{p_{\text{OG}}}{p_{\text{SIG}}} \right)^{e_{\text{OG}}},$$

$$S_i(\mathbf{p}, M^*) = S_i^r \left(\frac{p_i}{p_i^r} \right)^{e_i} / ST(\mathbf{p}, M^*) \quad i \in M^*,$$

$$S_i(\mathbf{p}, M^*) = 0 \quad i \notin M^*,$$

$$S_{\text{OG}}(\mathbf{p}, M^*) = S_{\text{OG}}^r \left(\frac{p_{\text{OG}}}{p_{\text{SIG}}} \right)^{e_{\text{OG}}} / ST(\mathbf{p}, M^*),$$

where e_i is the own-price share elasticity of item i , and e_{OG} analogously for the outside good. S_i^r and S_{OG}^r are the reference shares of item i and the outside good, respectively; they can be thought of as the intrinsic preference weights for the item. Quantity $ST(\mathbf{p}, M^*)$ normalizes the shares to ensure that they sum to unity. We take p_{OG} as fixed, since it is outside the control of the decision maker; note, however, that S_{OG}^r does depend on $\mathbf{p}$. This share model is equivalent to the widely used multiplicative competitive interaction (MCI) model due to Nakanishi and Cooper [13–16].

In its most basic form, demand Q_i of item i and demand Q_{OG} for the “outside” good is given by

$$Q_i(\mathbf{p}, M^*) = Q_{\text{SIG}}(\mathbf{p}, M^*) S_i(\mathbf{p}, M^*) \quad (2)$$

and

$$Q_{\text{OG}}(\mathbf{p}, M^*) = Q_{\text{SIG}}(\mathbf{p}, M^*) S_{\text{OG}}(\mathbf{p}, M^*).$$

Note that by definition we have $\sum_{i \in M^*} S_i(\mathbf{p}, M^*) + S_{\text{OG}}(\mathbf{p}, M^*) = 1$.

Assortment or Variety Effects. Retailer experience suggests that having a larger assortment, with greater variety, can lead to larger sales. This can be understood either as accommodating consumer heterogeneity, or as a consumer preference for variety [17]. We use a simple extension of the basic SIG demand model in Equation (1) to accommodate these effects:

$$\bar{Q}_{\text{SIG}}(\mathbf{p}, M^*) = \left[\left(Q_{\text{SIG}}^r \left(\frac{p_{\text{SIG}}(\mathbf{p}, M^*)}{p_{\text{SIG}}^r(M^*)} \right)^{e_{\text{SIG}}} \right) - Q_{\text{OG}}(\mathbf{p}, M^*) \right] |M^*|^{\delta_{\text{SIG}}},$$

where $0 < \delta_{\text{SIG}} < 1$ is the “assortment elasticity.” While this is not strictly elasticity, we adopt that label for expository convenience and restrict parameter values to model diminishing returns to assortment breadth. Note that here the effects of assortment on demand of an SIG depend only on the size of the assortment.

Presentation Effects. As is the case with the assortment or variety effects, retailers acknowledge that the extent of a presentation of an item is also correlated with sales for that item. A greater number of facings of an item will make it more prominent and attract more demand, and the more facings allocated to an item, the less likely that the display quantity will be depleted prior to restocking. We employ a simple extension of the basic item quantity model in Equation (2) to accommodate these effects:

$$Q_i(\mathbf{p}, M^*, f_i) = (\bar{Q}_{\text{SIG}}(\mathbf{p}, M^*) S_i(\mathbf{p}, M^*)) f_i^{\gamma_i},$$

where f_i is the number of “facings” of item i and $0 < \gamma_i < 1$ is the “presentation elasticity” of item i . Again, this is not strictly elasticity, but we adopt that label for expository convenience and restrict parameter values to model diminishing returns to presentation intensity. Finally, we note that if $f_i = 0$, there are no sales, which corresponds to the case of i being excluded from the assortment. The set of assorted items, M^* , is determined by $\mathbf{f} = (f_i)_{i \in M^*}$ as follows:

$$M^*(\mathbf{f}) = \{i \mid f_i > 0\}.$$

Full Model and Parameters. Combining all these elements, we have an item-level sales model that reflects the effects of prices on all items in the SIG, as well as the items that are assorted and the presentation, reflected in the number of facings of each item:

$$Q_i(\mathbf{p}, \mathbf{f}) = (Q_{\text{SIG}}(\mathbf{p}, M^*(\mathbf{f}))(1 - S_{\text{OG}}(\mathbf{p}, M^*(\mathbf{f}))) |M^*(\mathbf{f})|^{\delta_{\text{SIG}}} S_i(\mathbf{p}, M^*(\mathbf{f})) f_i^{\gamma_i}.$$

We are interested in the choices that confront the decision maker to set values for p_i and f_i

(and thus for M^* , as well). We assume that p_{OG} and p_i^r are fixed and given, and that $Q_{\text{SIG}}, S_i^r, S_{\text{OG}}^r, \delta_{\text{SIG}}, \gamma_i, e_i, e_{\text{SIG}}$, and e_{OG} are parameters to be set by expert judgment or to be calibrated from historical data.

Optimization Model

The decision problem is to choose the prices p_i and the number of facings f_i for each item in the SIG (which subsumes the problem of choosing the set of items to include in the assortment $M^*(\mathbf{f})$). In practice, a retailer may wish to maximize revenue, but, in concept, the optimization problem is to maximize some measure of gross profit. Thus, the model discussed in the previous section yields the following optimization problem:

$$\max_{\mathbf{p}, \mathbf{f}} \sum_{i \in M} (Q_{\text{SIG}}(\mathbf{p}, M^*(\mathbf{f}))(1 - S_{\text{OG}}(\mathbf{p}, M^*(\mathbf{f}))) |M^*(\mathbf{f})|^{\delta_{\text{SIG}}} S_i(\mathbf{p}, M^*(\mathbf{f})) f_i^{\gamma_i} (p_i - c_i),$$

where $p_i - c_i$ is the gross profit for item i .

The dominant constraint in this problem is the space constraint. We assume that each item occupies a certain amount of linear shelf space, per facing. If we have K_{SIG} linear space allocated to the SIG, then we have

$$\sum_{i \in M} w_i f_i \leq K_{\text{SIG}},$$

where w_i is the width of item i . Typically, there are other business constraints, such as an item being required to be assorted, or the maximum space that can be allocated to an item. These can be condensed into a set of range constraints for each item:

$$l_i \leq f_i \leq u_i,$$

where l_i and u_i are minimum and maximum allowable number of facings for item i . It is also typical that there are limits on the magnitude of price changes. For simplicity, we assume that the current prices are the reference prices, which yields for each item constraints

$$p_i^r(1 - \theta_i) \leq p_i \leq p_i^r(1 + \theta_i),$$

where θ_i is the maximum allowable price change of item i .

This model is hard to solve; however, we resort to the fact that the number of items in the SIG is relatively low. To this end, the algorithm enumerates all possible assortments M , and for each of them we solve the resulting nonlinear continuous optimization problem.

CONCLUSION

Models much like the promotion forecasting model in the section titled “Forecasting” are presently used by managers in some retail chains, both for the purposes of planning promotions and improving supply chain decisions. The assortment, space, and price optimization model in the section titled “Optimization” is the subject of active research, but, to the authors’ knowledge, it is not employed at present in a production system. K  k and Fisher [18] present estimation results and management implications from implementing a similar model at a European grocery retailer.

Retailing has been imagined to be “a paradise for operations researchers” [12]. It is rich with interesting problems and an increasing appetite for adapting to some of the methods and tools of OR. We have described a few areas where the fertile interplay between academic research, analytic solution vendors and consultants, and retail decision makers is yielding new and useful OR applications.

ANT COLONY OPTIMIZATION

MARCO DORIGO
MARCO A. MONTES DE OCA
SABRINA OLIVEIRA
THOMAS STÜTZLE
IRIDIA, CoDE, Université Libre de
Bruxelles (ULB), Brussels,
Belgium

Ant colony optimization (ACO) [1–8] is a class of algorithms for tackling optimization problems that is inspired by the pheromone trail laying and following behavior of some ant species. While foraging, ants leave on the ground a chemical substance, called *pheromone*, that attracts other fellow nest-mates [9]. The pheromone trail laying and following behavior of the ants induces a positive feedback process whereby trails with high concentration of pheromones become more and more attractive as more ants follow them [10–12]. As a result, whenever two paths to the same food source are discovered, the colony is more likely to select the shortest one because ants will traverse it faster and thus it will have a higher pheromone concentration than the longer one.

ACO algorithms exploit a mechanism analogous to the one that allows colonies of real ants to find shortest paths. In ACO, (artificial) ants construct candidate solutions to the problem instance under consideration. Their solution construction is stochastically biased by (artificial) pheromone trails, which are represented in the form of numerical information that is associated with appropriately defined solution components, and possibly by heuristic information based on the input data of the instance being solved. A key aspect of ACO algorithms is the use of a positive feedback loop implemented by iterative modifications of the artificial pheromone trails that are a function of the ants' search experience; the goal of this feedback loop is to bias the colony toward the most promising solutions.

The ACO metaheuristic is a high-level algorithmic framework for applying the above ideas to the approximate solution of optimization problems. When applied to a specific optimization problem, this ACO framework needs to be concretized by taking into account the specifics of the problem under consideration and possibly by adding additional techniques such as problem-specific solution improvement procedures. The development of effective ACO algorithm variants has been one of the most active research directions in ACO: this article gives an overview of the most important of these developments. For more information about successful applications of ACO, we refer to the article titled ***A Concise Overview of Applications of Ant Colony Optimization***, in this encyclopedia.

ACO EXAMPLE APPLICATIONS

Perhaps the easiest way to understand how ACO algorithms work is through examples. Here, we present two examples where the ACO algorithms use different solution representations. The first example shows how ACO is applied to solve the traveling salesman problem (TSP), which was the first optimization problem to which an ACO algorithm was applied. The second example concerns the set covering problem (SCP): it shows how ACO algorithms can be used to solve problems using a binary representation.

Example 1. Ant Colony Optimization for the Traveling Salesman Problem

The TSP is one of the most widely studied combinatorial optimization problems. It is also a problem to which the application of ACO algorithms is rather intuitive and straightforward. An instance of the TSP is determined by a set of locations (cities) and by the distances between them. The goal is to find a closed tour of minimal length that visits each city exactly once. A TSP instance

can be represented by a fully connected graph $G = (V, E, d)$, V being the set of $n = |V|$ vertices (representing the cities), E being the set of edges that fully connects the vertices, and d being a distance function that assigns to each edge (i, j) a distance d_{ij} . Here, we assume that the distance function is symmetric, that is, we have $d_{ij} = d_{ji}$, meaning that the distance is the same whether one goes from i to j or in the opposite direction.

To tackle a TSP instance with an ACO algorithm, each edge $(i, j) \in E$ needs a pheromone value τ_{ij} associated with it. The pheromone values are represented by real numbers that are modified while running the algorithm; they reflect the *learned* desirability of choosing an edge: the higher the pheromone value τ_{ij} , the higher is the desirability of choosing edge (i, j) as a solution component. Additionally, each edge has an associated heuristic value $\eta_{ij} = 1/d_{ij}$. For the TSP, the value η_{ij} is a measure of the *heuristic* desirability of having edge (i, j) as a component of a tour: the shorter the distance, the higher is the heuristic desirability.

An intuitive approach for constructing a tour is to first choose a vertex randomly and then, at each step, to go from the current vertex to the closest one that has not yet been visited. This solution construction ends when all vertices have been visited and the round trip is closed by returning to the initial vertex. In all ACO algorithms that have been implemented so far, the ants follow a randomized version of this construction rule. In fact, at each construction step, they choose randomly a next vertex based on the pheromone trail information and the heuristic information. The probabilistic choice is biased by pheromone and heuristic values: the higher the pheromone and the heuristic values associated with an edge, the higher the probability that an ant will choose it. Once all ants have completed their tours, the pheromone on the edges is updated. First, all pheromone values are decreased by a constant factor, simulating the phenomenon of pheromone evaporation. Then, each edge receives an amount of pheromone proportional to the quality of the solutions to which it belongs (there is one solution per ant); that is, the shorter the associated tour, the more

pheromone is deposited on the edges, making them more attractive in future iterations.

Example 2. Ant Colony Optimization for the Set Covering Problem

The SCP is a problem in which a candidate solution is represented by a subset of elements from some other set subject to some feasibility constraints. In the SCP, one is given two sets A and B . Each element B_i of B is a subset of A and it has associated a cost c_i . The goal of the SCP is to find a subset of the set B of minimal cost such that A is covered, that is, every element of the set A occurs in at least one of the elements chosen from set B . To guarantee that such a solution exists, one necessary assumption to make is that the elements of B cover the set A , that is, $\bigcup_{i=1}^n B_i = A$. A candidate solution for the SCP can be represented by an n -dimensional binary vector $X = [x_i]$, where n is the cardinality of set B , $x_i = 1$ if B_i is selected to be part of the solution, otherwise $x_i = 0$.

For solving an instance of the SCP with an ACO algorithm, we define the solution components as the elements of the set B . Each set B_i has associated a pheromone trail τ_i . The pheromone trails represent, analogous to the TSP, the ants' cumulated experience in solving the problem. For the SCP, the pheromone τ_i gives the desirability for an ant to choose element B_i , that is, to set the decision variable $x_i = 1$. The heuristic information η_i can be defined in various ways. One possibility is to use $\eta_i = k_i/c_i$, where $k_i = |B_i|$ is the total number of elements covered by the subset B_i . Hence, the heuristic function gives the average cost for B_i of covering elements of A . In this case, the heuristic information makes use only of *a priori* available information. It is therefore possible to compute the heuristic information before running the algorithm and therefore to compute the values of $\tau_i \cdot \eta_i$ before each algorithm iteration, saving in this way computation time. However, it may be advantageous to make the heuristic information more accurate (but slower to compute) by taking into account an ant's partial solution. In the SCP case, η_i could then measure the unit cost of covering one additional, still uncovered element of set A . This can be done by using $\eta_i = e_i/c_i$, where e_i is the number of

additional elements of set A covered when B_i is added to an ant's partial solution. Which of the two options—using the faster but less accurate precomputed heuristic information or adapting the heuristic information based on the ants' partial solutions—is preferable typically depends on the particular problem to which ACO is applied.

Ants construct solutions taking into account both the pheromone value and the heuristic information associated with each solution component. In the SCP case, an ant starts with an empty solution and chooses, at each construction step, one element of B until all elements of A are covered. In other words, an ant starts with all decision variables set to zero and at each construction step it sets one decision variable to one until all elements of A occur in at least one of the chosen elements of B . Note that in the SCP application, the number of construction steps to complete a solution may differ among the ants. Once each ant has terminated the construction of a candidate solution, it can remove subsets B_i that may have become redundant while constructing a solution before the pheromone trails are updated.

ACO METAHEURISTIC

ACO can be applied to any combinatorial optimization problem for which it is possible to devise an incremental solution construction procedure. Let us consider a general description of a combinatorial optimization problem that is modeled by the tuple (S, f, Ω) , where

- S is the set of candidate solutions defined over a finite set of discrete decision variables $\mathbb{X}$. S is referred to as the *search space* of the problem being tackled;
- $f: S \rightarrow \mathbb{R}$ is an objective function to be minimized;
- Ω is a (possibly empty) set of constraints among the decision variables.

A decision variable $X_i \in \mathbb{X}$, with $i = 1, \dots, n$, is said to be instantiated when a value v_i^j that belongs to its domain

```

procedure ACOMetaheuristic
  ScheduleActivities
    ConstructSolutions
    DaemonActions //optional
    UpdatePheromones
  end-ScheduleActivities
end-procedure

```

Figure 1. ACO metaheuristic in pseudocode. It works by intertwining three high-level procedures: ConstructSolutions, DaemonActions, and UpdatePheromones.

$D_i = \{v_i^1, \dots, v_i^{|D_i|}\}$ is assigned to it. A solution $s \in S$ is called *feasible* if each decision variable has been instantiated satisfying all constraints in the set Ω . Solving the optimization problem requires finding a solution s^* such that $f(s^*) \leq f(s) \forall s \in S$. Note that maximizing the value of an objective function f is the same as minimizing the value of $-f$; hence, every model of a combinatorial optimization problem can be described as a minimization problem.

ACO works by intertwining three high-level procedures: ConstructSolutions, DaemonActions, and UpdatePheromones as shown in Fig. 1. The ScheduleActivities construct does not specify how the three algorithmic components are scheduled and synchronized. However, in most applications, these procedures are executed in the depicted order.

- *ConstructSolutions.* This procedure implements the artificial ants' incremental construction of candidate solutions. In ACO, an instantiated decision variable $X_i \leftarrow v_i^j$ is called a *solution component* $c_{ij} \in C$, where C denotes the set of solution components. A pheromone trail value τ_{ij} is associated with each component $c_{ij} \in C$. (More formally, each solution component has an associated pheromone variable that can take a value, the pheromone trail value, in a specific range.) A solution construction starts from an initially empty partial solution s^p . At each construction step, s^p is extended by appending to it a feasible solution component from the set of its feasible neighbors $N(s^p) \subseteq C$ that satisfies the constraints in Ω . The

choice of a solution component is guided by a stochastic decision policy, which is biased by both the pheromone trail and the heuristic values associated with c_{ij} . The exact rules for the probabilistic choice of solution components vary across different variants of ACO. The best known rule is the one used first in the ant system algorithm [4]

$$p_{c_{ij}|s^p} = \frac{[\tau_{ij}]^\alpha \cdot [\eta_{ij}]^\beta}{\sum_{c_{il} \in N(s^p)} [\tau_{il}]^\alpha \cdot [\eta_{il}]^\beta}, \quad (1)$$

where τ_{ij} and η_{ij} are, respectively, the pheromone trail value and the heuristic value associated with the component c_{ij} . The parameters $\alpha > 0$ and $\beta > 0$ determine the relative importance of pheromone versus heuristic information.

- *DeamonActions*. This procedure, although optional, is important when state-of-the-art results are sought [7]. It allows the execution of problem-specific operations, such as the use of local search procedures, or of centralized actions that cannot be performed by artificial ants. It is usually executed before the update of pheromone values in order to bias the ants' search toward high quality solutions.
- *UpdatePheromones*. This procedure updates the pheromone trail values associated with the solution components in the set C . The modification of the pheromone trail values is performed in two stages: (i) *pheromone evaporation*, which decreases the pheromone values of all components by a constant factor ρ (called *evaporation rate*) in order to avoid premature convergence, and (ii) *pheromone deposit*, which increases the pheromone trail values associated with components of a set of promising solutions S_{upd} . The general form of the pheromone update rule is as follows:

$$\tau_{ij} \leftarrow (1 - \rho) \cdot \tau_{ij} + \rho \cdot \sum_{s \in S_{upd} | c_{ij} \in s} F(s), \quad (2)$$

where $\rho \in (0, 1]$ is the evaporation rate, and $F: S \rightarrow \mathbb{R}^+$ is a function such that $f(s) < f(s') \Rightarrow F(s) \geq F(s')$, $\forall s \neq s' \in S$. $F(\cdot)$ is called the *fitness function*. Different definitions for the set S_{upd} exist. Two common choices are $S_{upd} = s_{bsf}$, and $S_{upd} = s_{ib}$, where s_{bsf} is the best-so-far solution, that is, the best solution found since the start of the algorithm, and s_{ib} is the best solution of the current iteration. The specific implementation of the pheromone update mechanism differs across ACO variants [1,4,13–15].

When applying the ACO metaheuristic to a specific problem, the definition of solution components and, hence, the definition of the interpretation of the pheromone trails is decisive for the final performance of the ACO algorithm. In fact, even when restricting to problems where candidate solutions can be represented by a same representation (e.g., permutations), different interpretations for solution components and pheromone trails may be useful. For example, while in the TSP case (see Example 1 in the previous section), the successor relationship is important, that is, τ_{ij} should refer to the desirability of visiting city j directly after city i , in scheduling applications, it is often preferable to interpret a pheromone trail τ_{ij} as the desirability of assigning a job j to position i . When facing problems for which several alternative definitions of pheromone are reasonable, which one would be the best choice has to be determined experimentally.

ACO ALGORITHMS

The ACO metaheuristic is a general algorithmic framework. Various specific ACO algorithms, which all follow the high-level rules of the ACO metaheuristic, have been proposed in the literature. In fact, these variants are obtained by various instantiations of the three main procedures that build the ACO metaheuristic. Some of the most noteworthy variants are described below.

Ant System

Ant System (AS) was the first ACO algorithm reported in the literature [2–4]. In AS, the

pheromone values are updated at each iteration by all m ants of the colony. All pheromone trail values τ_{ij} are updated as follows:

$$\tau_{ij} \leftarrow (1 - \rho) \cdot \tau_{ij} + \sum_{k=1}^m \Delta\tau_{ij}^k, \quad (3)$$

where ρ is the evaporation rate, and $\Delta\tau_{ij}^k$ is the quantity of pheromone laid on c_{ij} by ant k . $\Delta\tau_{ij}^k$ is defined as follows:

$$\Delta\tau_{ij}^k = \begin{cases} F(s_k) & \text{if component } (i,j) \text{ is in the} \\ & \text{solution constructed by ant } k, \\ 0 & \text{otherwise,} \end{cases} \quad (4)$$

where the value of $F(s_k)$ is a function of the quality of the solution constructed by ant k . Normally, the better the solution, the higher is the amount of pheromone deposited.

In the solution construction, ants select solution components according to a stochastic mechanism, following Equation (1).

AS is mainly of historical interest because it was the first ACO algorithm proposed in the literature. Initial computational results have been interesting in the sense that they showed that the underlying mechanism works and allows to find good quality solutions. However, the performance of AS was still quite far from state-of-the-art methods. The main importance of AS is that it has seeded follow-up work by various researchers on better performing algorithmic variants, such as the two presented next.

$\mathcal{MAX}\text{-}\mathcal{MIN}$ Ant System

$\mathcal{MAX}\text{-}\mathcal{MIN}$ Ant System ($\mathcal{MMAS}$) [15] is an improvement over the original Ant System. Its main features are (i) only one of the best ants deposits pheromone, and (ii) the range of the allowed pheromone trail values is bounded. The pheromone update is implemented as follows:

$$\tau_{ij} \leftarrow \begin{cases} \tau_{\min} & \text{if } \tau_{ij} < \tau_{\min}, \\ (1 - \rho) \cdot \tau_{ij} + \Delta\tau_{ij}^{\text{best}} & \text{if } \tau_{\min} \leq \tau_{ij} \leq \tau_{\max}, \\ \tau_{\max} & \text{if } \tau_{ij} > \tau_{\max}, \end{cases} \quad (5)$$

where $\tau_{\max}$ and $\tau_{\min}$ are, respectively, the upper and lower bounds imposed on the pheromone, and $\Delta\tau_{ij}^{\text{best}}$ is defined as

$$\Delta\tau_{ij}^{\text{best}} = \begin{cases} F(s_{\text{best}}) & \text{if solution component } (i,j) \\ & \text{is part of } s_{\text{best}}, \\ 0 & \text{otherwise,} \end{cases} \quad (6)$$

where the value of $F(s_{\text{best}})$ is a function of the quality of the best solution found. This solution can be s_{ib} , s_{bsf} , a combination of them, or possibly some other high-quality solution.

Concerning the lower and upper bounds on the pheromone values, a bound on the maximum value may be calculated analytically as $\tau_{\max}^b = F(s^*)/\rho$, if the optimal solution s^* is known [16]. If s^* is not known, it can be approximated by s_{bsf} . Usually, setting $\tau_{\max} = \tau_{\max}^b$ (or to its approximation) results in good behavior of $\mathcal{MMAS}$. The initial value of the trails is set to $\tau_{\max}$ to increase the diversification of the search at the start of the algorithm. Some heuristic considerations for defining the setting of $\tau_{\min}$ have been proposed [15,17]. Finally, $\mathcal{MMAS}$ was the first ACO algorithm to use additional mechanisms for increasing the diversification of the search such as a reinitialization of the pheromone trails or a smoothing of the pheromone trail values when no improvement is observed for a given number of iterations. For a detailed description of these mechanisms, a general overview of $\mathcal{MMAS}$, and some variants of $\mathcal{MMAS}$, we refer the reader to [17].

Ant Colony System

Ant Colony System (ACS) [13] differs in some key aspects from other ACO algorithms. The first is that it uses a different decision rule in the ants' solution construction, which is known as the *pseudorandom proportional rule*. In this rule, with probability q_0 the next solution component j is the one that maximizes the product of the pheromone and heuristic values, that is, $j = \arg \max_{c_{il} \in N(s^p)} \{\tau_{il} \eta_{il}^\beta\}$. With probability $1 - q_0$ the probabilistic choice is made using Equation (1).

Similar to $\mathcal{MMAS}$, a pheromone update is applied at the end of each iteration by only one ant. The ACS pheromone update formula is as follows:

$$\tau_{ij} \leftarrow \begin{cases} (1 - \rho) \cdot \tau_{ij} + \rho \cdot \Delta\tau_{ij}^{\text{best}} & \text{if solution} \\ & \text{component } (i,j) \text{ is part of } s_{\text{best}}, \\ \tau_{ij} & \text{otherwise.} \end{cases} \quad (7)$$

As in $\mathcal{MMAS}$, $\Delta\tau_{ij}^{\text{best}} = F(s_{\text{best}})$, where s_{best} can be either s_{ib} or s_{bsf} . It is noteworthy that in ACS only the pheromone values of solution components associated with the best solution are updated.

To avoid search stagnation, in ACS a local pheromone update is performed by each ant after each construction step. This update decreases the pheromone trail value of the solution component that has been chosen in the previous step. The goal is to diversify the search performed by subsequent ants during an iteration: by decreasing the pheromone concentration for chosen components, these get less desirable for subsequent ants, thus increasing the chances of producing different solutions. Each ant applies the local pheromone update only to the pheromone trail of the last solution component added

$$\tau_{ij} \leftarrow (1 - \varphi) \cdot \tau_{ij} + \varphi \cdot \tau_0, \quad (8)$$

where $\varphi \in (0, 1)$ is a parameter called *pheromone decay coefficient*, and τ_0 is a parameter that determines the initial value for the pheromone trails. A good value for τ_0 was found to be $F(s^h)/n$, where n is the size of the instance and s^h is a solution constructed using a problem-specific heuristic [7].

Other Variants

In addition to the variants described above, there are others that have been reported in the literature. Table 1 summarizes the main ACO variants, including those discussed in the previous sections, which have been proposed in the literature for the approximate solution of NP-hard problems. For each of these variants, we give the main references and the year in which they were proposed.

The main characteristics of the ACO algorithms that were not discussed so far are the following. Elitist AS is a direct variant of AS that gives a strong additional feedback to the best solution constructed since the start of the algorithm. Ant-Q is a predecessor of ACS that is inspired by the well-known Q-learning method from reinforcement learning. Rank-based AS extends Elitist AS by allowing not only the best-so-far ant, but also the r best ranked ants of the current iteration to deposit pheromone; the weight given to each ant in the pheromone update is inversely proportional to its rank, the highest weight being given to the best-so-far ant. ANTS is an ACO algorithm that exploits the connection with tree-search procedures by including elements from branch-and-bound techniques, such as lower bound information, into an ACO algorithm. Best-worst AS is an AS variant where the worst ant of the current iteration is used to subtract pheromone from solution components that are part of this worst ant but that do not occur in the best-so-far solution. Population-based ACO uses a set of elite solutions to define, at each iteration, the pheromone trail matrix. The set of elite solutions is managed by a population management mechanism that is responsible for updating the pheromone matrix each time a solution is added or removed from the elite set. Finally, Beam-ACO incorporates a heuristic derived from branch-and-bound algorithms called *beam search*.

Table 1. Overview of the main ACO algorithms for NP-hard problems that have been proposed in the literature

ACO Algorithm	Main References	Year
Ant System (AS)	[2–4]	1991
Elitist AS	[2–4]	1992
Ant-Q	[18]	1995
Ant Colony System	[13,14]	1996
$\mathcal{MAX-MIN}$ AS	[15,19,20]	1996
Rank-based AS	[21,22]	1997
ANTS	[23,24]	1998
Best-worst AS	[25,26]	2000
Population-based ACO	[27]	2002
Beam-ACO	[28,29]	2004

Given are the ACO algorithm names, the main references where these algorithms are described, and the year in which they were first published.

Hybrid ACO Algorithms

Currently, it is a well-established fact that ACO algorithms reach best performance for most combinatorial optimization problems when they are combined with either iterative improvement algorithms or more complex local search methods such as tabu search or simulated annealing [7]. In these hybrid algorithms, the local improvement methods are used to improve the solutions constructed by one or more ants after each iteration. The usage of local search algorithms is also one example of the daemon actions that have been mentioned in the description of the ACO metaheuristic (see Fig. 1).

Various alternative ways of hybridizing ACO algorithms with other techniques have been studied. The ANTS and Beam-ACO algorithms, mentioned in the previous section, were explicitly designed as hybrid algorithms that integrate features from branch-and-bound techniques into ACO algorithms. Another active area is the integration of constraint programming techniques into ACO algorithms [30,31], which is particularly attractive for problems where, due to the problem constraints, it is difficult for the ants to generate feasible candidate solutions. Other hybrid techniques exploit the idea of using partial candidate solutions to seed an ant's solution construction. Examples of these hybrid methods are the use of external memory in ACO algorithms [32] or the extensions called *iterated ants* [33] and *cunning ants* [34].

The investigation of hybrid ACO algorithms is currently one of the most active areas in the research on ACO.

ACO APPLICATIONS

ACO algorithms have been successfully applied to a large variety of important problems from both the academic and industrial worlds (see the article ***A Concise Overview of Applications of Ant Colony Optimization*** for more information). The main application areas are the following:

NP-Hard Problems. The best known algorithms that are guaranteed to

find an optimal solution to this kind of problems have exponential time complexity in the worst case [35]. However, heuristic methods such as ACO can be used to find high-quality solutions in a reasonable amount of time. Some examples of NP-hard problems for which ACO algorithms have been successful are *routing problems* [36–38], in which the goal is to find the shortest route that visits a set of locations; *assignment problems* [15], where a set of items (objects, activities, etc.) has to be assigned to a given number of resources (locations, agents, etc.) subject to some constraints; *subset problems* [39], where a solution to a problem is considered to be a selection of a subset of available items; and *scheduling problems* [29], in which the main concern is to optimally allocate scarce resources to tasks over time.

Rich Academic and Industrial Problems.

After initial encouraging results on classic academic problems, ACO started to be applied to real industrial problems such as those arising in the food or in manufacturing industry [38,40]. As a result, richer versions of the academic problems started to be studied. Among the features of these problems are time-varying data [41], stochasticity [42,43], the presence of multiple objectives [44,45], continuous variables [46], mixed variables [47], and so on. Practically relevant dynamic problems are those found in the domain of telecommunication networks because some important properties, such as the cost of using links or the availability of nodes, vary over time. Some ACO algorithms have been shown to be very effective at solving these types of problems [48–50].

ACO THEORY

Most of the research results on metaheuristics, in general, and on ACO, in particular, are of experimental nature. However,

there is also a significant interest in more fundamental properties of ACO algorithms.

A first question that is usually asked is whether, given enough time, the algorithm will eventually find an optimal solution. An initial answer to this question was given by Gutjahr, who proved for an ACO algorithm called *graph based ant system* (GBAS) the convergence with probability $1 - \epsilon$ to the optimal solution [51]. In a later paper [52], convergence with probability 1 was proven for two variants of GBAS. While GBAS has not been studied in practical applications, it is remarkable that convergence proofs for two of the practically most successful ACO algorithms, ACS and $\mathcal{MMAS}$, have also been obtained [53]. More recently, the focus of research has shifted to studies of the expected runtime to find optimal solutions in ACO applications to specific problems. An overview of proof techniques and some results are given by Gutjahr [54]; recent publications in this direction can be found in [55–57].

Other contributions on theoretical aspects of ACO have focused on establishing connections to other methods. Zlochin *et al.* [58] have defined the framework of model-based search algorithms, of which ACO is one representative. Connections of ACO to stochastic gradient descent, an algorithm used, for example, for learning weights in neural networks, have been studied in [59]. Of more practical interest are studies on the behavior of ACO algorithms. Merkle and Middendorf were the first to analyze the dynamic behavior of the pheromone model in ACO algorithms [60]. Search bias in ACO algorithms is studied in [61], where the authors show that ACO algorithms may suffer from the same type of deception as evolutionary algorithms do. In addition, they show that ACO algorithms may suffer from what they call a second order deceptive behavior, where, due to an interaction between the pheromone update and the pheromone model chosen, the quality of the solutions generated by an ACO algorithm can decrease over time.

A more detailed discussion of theoretical results about ACO algorithms is given in [7,62].

CONCLUSIONS

ACO is now one of the main metaheuristics and an active area of research. Early research on ACO focused mainly on the development of effective ACO algorithm variants and a common framework for these algorithmic developments is given by the ACO metaheuristic. Currently, the main active research directions in ACO concern applications to computationally challenging problems, the hybridization of ACO algorithms with other search techniques, and the theoretical study of the behavior of specific ACO algorithms.

Evidence of the success of ACO algorithms is the number of specialized meetings, where researchers can discuss their research results on ACO algorithms and their applications. ACO is one of the main subjects of the biannual conference ANTS (International Conference on Swarm Intelligence; <http://iridia.ulb.ac.be/ants/>) and of the IEEE Swarm Intelligence Symposium series. In addition, ACO is a central topic at various conferences on metaheuristics and evolutionary algorithms. Finally, research on ACO has frequently been featured in journal special issues [63–66] and is a fundamental subject of the journal *Swarm Intelligence*. Information on ACO and related topics can be obtained through the moderated mailing list `aco-list`, and the ACO web page (www.aco-metaheuristic.org).

ANTITHETIC VARIATES

DONGHAI HE

CHUN-HUNG CHEN

Department of Systems Engineering and
Operations Research, George Mason
University, Fairfax, Virginia

One of the most recommended variance reduction techniques for Monte Carlo simulation is antithetic variates, first introduced by Hammersley and Morton [1]. It was motivated by the desire to achieve a smaller variance than simple Monte Carlo random sampling could obtain from simulation samples of the same size. The basic idea is to induce negative correlation into random samples. This survey article gives an overview of antithetic variates and discusses their recent development. Numerical results are presented to illustrate their effectiveness.

Originally, the antithetic variates method was developed to allow for the evaluation of integrals by Monte Carlo sampling methods with better accuracy (smaller variance) than one could achieve for a given sample size with pure random sampling, when the integral function is bounded. Wilson [2] shows that unbounded functions are also suitable for antithetic variates method. Instead of focusing on integrals, Page [3] extends antithetic variates to estimate the statistics of queueing system simulation. Furthermore, Mitchell [4] applies antithetic variates to $GI/G/1$ queueing models and extends certain results obtained by Page [3]. George [5] uses antithetic variates to reduce the variance of prediction of replacement requirements in a multiple-component multiple-period replacement process. Nelson [6] applies antithetic variates to obtain better estimates of steady-state simulations. Avramidis and Wilson [7] extend antithetic variates to estimate quantiles instead of expected values. Further, antithetic variates have been successfully applied to Monte Carlo radiation transport problems [8]

and particle transport problems [9]. Cheng [10], L'Ecuyer [11], and Law and Kelton [12] present a nice overview of antithetic variates. More discussions on antithetic variates can be found in Refs 13–21.

The rest of this article is organized as follows: we first present fundamental statistics and then explain the basic ideas of antithetic variates. We show how they work to reduce variance in Monte Carlo simulation. Limitations of current antithetic variates methods are then discussed, and new developments presented. Finally, we conduct two numerical experiments to demonstrate the effectiveness of antithetic variates. The numerical results illustrate what can be expected from this variance reduction method.

FUNDAMENTAL AND BASIC IDEAS

The basic idea of antithetic variates is to construct pairs of simulation samples such that a small observation in one of the samples tends to be offset by a bigger observation in the other. As a result, the average of these two observations will tend to be closer to the mean value we are trying to estimate. To achieve that, the observations must be negatively correlated. We start with a simple case.

Suppose X_1 and X_2 are two simulation samples. The mean is estimated using a sample mean estimator

$$\bar{X} = \frac{1}{2}(X_1 + X_2).$$

When X_1 and X_2 are independent, the variance of the sample mean estimator is

$$\text{Var}(\bar{X}) = \frac{1}{4}[\text{Var}(X_1) + \text{Var}(X_2)].$$

If we introduce negative correlation between these two samples, then

$$\begin{aligned} \text{Var}(\bar{X}) &= \frac{1}{4}[\text{Var}(X_1) + \text{Var}(X_2) + 2\text{Cov}(X_1, X_2)] \\ &< \frac{1}{4}[\text{Var}(X_1) + \text{Var}(X_2)]. \end{aligned} \quad (1)$$

The higher the negative correlation between X_1 and X_2 , the more we can reduce the variance of the sample mean estimator.

Now consider a general case. Suppose

$$X = f(W) \quad (2)$$

is an unbiased estimator of interest, where $f(\cdot)$ is either a bounded or an unbounded function with finite variance [2], and W is the random input. The goal is to estimate the expected value of X . In the setting of Monte Carlo simulation, we take n samples of W and so obtain n samples of X . Then the expected value of X can be estimated as

$$\bar{X}(n) = \frac{1}{n} \sum_{i=1}^n X_i = \frac{1}{n} \sum_{i=1}^n f(W_i), \quad (3)$$

where W_i is the i th random input, X_i is the i th response (or observation), $\bar{X}(n)$ denotes the sample mean and n is the sample size. The variance of $\bar{X}(n)$ is

$$\begin{aligned} \text{Var}(\bar{X}(n)) &= \frac{1}{n^2} \text{Var} \left(\sum_{i=1}^n X_i \right) \\ &= \frac{1}{n^2} \left(\sum_{i=1}^n \text{Var}(X_i) + 2 \sum_{i=1}^n \sum_{j=i+1}^n \text{Cov}(X_i, X_j) \right). \end{aligned} \quad (4)$$

If X_i and X_j , for $i \neq j$, $i, j \in \{1, \dots, n\}$, are negatively correlated, the variance of the sample mean estimator is reduced. The question is how to induce negative correlation among the samples.

INDUCING NEGATIVE CORRELATION

In Monte Carlo simulation, random variates are normally generated using uniform random numbers. Hammersley and Morton [1] induce negative correlation in these random numbers while ensuring that the estimator of interest remains unbiased. In the simplest form of antithetic variates, the negative correlation is induced by using *complementary* random numbers. Define

$$W_i^{(1)} = U_i$$

$$\text{and } W_i^{(2)} = 1 - U_i,$$

where $W_i^{(1)}$ and $W_i^{(2)}$ constitute the i th pair of antithetic variates, and the random number U_i is uniformly distributed between 0 and 1. Note that

$$\text{Cov}(W_i^{(1)}, W_i^{(2)}) = -\text{Var}(U_i) < 0.$$

By introducing antithetic variates, Equation (3) can be rewritten as

$$\bar{X}(n) = \frac{1}{n} \sum_{i=1}^{n/2} [f(W_i^{(1)}) + f(W_i^{(2)})]. \quad (5)$$

Thus, the variance of $\bar{X}(n)$ in Equation (4) can be rewritten as

$$\begin{aligned} \text{Var}(\bar{X}(n)) &= \frac{1}{n^2} \text{Var} \left(\sum_{i=1}^{n/2} [f(W_i^{(1)}) + f(W_i^{(2)})] \right) \\ &= \frac{1}{n^2} \left(\sum_{i=1}^{n/2} \text{Var}(f(W_i^{(1)})) \right. \\ &\quad \left. + \sum_{i=1}^{n/2} \text{Var}(f(W_i^{(2)})) \right. \\ &\quad \left. + 2 \sum_{i=1}^{n/2} \text{Cov}(f(W_i^{(1)}), f(W_i^{(2)})) \right). \end{aligned} \quad (6)$$

When $f(W_i^{(1)})$ and $f(W_i^{(2)})$ are simulated independently, the covariance terms are zero. If we induce negative correlation between them, $\text{Cov}(f(W_i^{(1)}), f(W_i^{(2)})) < 0$ and the variance of $\bar{X}(n)$ is reduced.

Note that the simulation output responses, $f(W_i^{(1)})$ and $f(W_i^{(2)})$, are not always negatively correlated, even when the random inputs, $W_i^{(1)}$ and $W_i^{(2)}$, are negatively correlated. Hammersley and Morton [1] show that if the response function $f(\cdot)$ is a monotone, increasing or decreasing, then $\text{Cov}(f(W_i^{(1)}), f(W_i^{(2)})) \leq 0$. On the other hand, Cheng [22,23] demonstrates that $\text{Cov}(f(W_i^{(1)}), f(W_i^{(2)}))$ might be positive if the response function is not a monotone, in which case the variance increases.

Nonuniform Random Input

In most cases, the random inputs are not uniformly distributed. For example, the interarrival and service times in an $M/M/1$ queueing model follow exponential distributions. To ensure negative correlation, we generate random inputs using the inverse transform method. Thus,

$$W^{(1)} = g(U) \\ \text{and } W^{(2)} = g(1 - U),$$

where $g(\cdot)$ is an inverse cumulative distribution function (ICDF). The correlation coefficient between U and $1 - U$ is

$$\begin{aligned} \rho_{U,1-U} &= \frac{\text{Cov}(U, 1 - U)}{\sqrt{\text{Var}(U) \cdot \text{Var}(1 - U)}} \\ &= \frac{-\text{Var}(U)}{\text{Var}(U)} = -1. \end{aligned}$$

However, the correlation coefficient between $W^{(1)}$ and $W^{(2)}$, $\rho_{W^{(1)}, W^{(2)}}$, may be much greater than -1 due to the transformation of $g(\cdot)$.

Page [3] and Franta [24] show that if $W^{(1)}$ and $W^{(2)}$ are a pair of normally distributed antithetic variates generated by the Box Muller method (polar method), $\rho_{W^{(1)}, W^{(2)}} \approx -0.582$. If they are generated by the Marsaglia method, $\rho_{W^{(1)}, W^{(2)}} = -1$. If $W^{(1)}$ and $W^{(2)}$ are a pair of exponentially distributed (with parameter 1) antithetic variates, in which case the ICDF $g(u) = -\log(u)$, then $\rho_{W^{(1)}, W^{(2)}} = -0.645$.

In addition to the inverse transform method, random variates can be generated using other approaches. Schmeiser and Kachitvichyanukul [25] develop fast approaches to generate correlated random inputs using composition and acceptance/rejection methods. However, these approaches produce less correlation than that obtained by the inverse transform method.

Extensions

Several extensions and variations of the antithetic variates method have been developed.

Multivariate Inputs. Wilson [26] extends antithetic variates to the case of two or more

random variables. Consider an unbiased estimator which is a summation of m responses of random inputs:

$$\sum_{j=1}^m f_j(W_j). \quad (7)$$

Instead of using complementary random numbers between samples (e.g., U and $1 - U$), a key step of this extension consists of inducing appropriate dependencies among these input random variables while preserving their distributions. Intuitively, this estimator should be composed of mutually counteracting random variables so that the sum has a small net variance. Wilson [26] also offers a general framework, with antithetic variate theorems, in attempting to minimize the variance of the estimator given in Equation (7).

Fishman and Huang [27] extend antithetic variates to multivariate inputs in an estimator similar to Equation (7). Like Wilson [26], instead of using U and $1 - U$ between simulation samples, they intend to induce the desired negative correlation among these m responses in a sample using a rotation sampling scheme. One example of rotation sampling is

$$W_j(U) = \begin{cases} U + \theta_j & 0 \leq U < 1 - \theta_j \\ U + \theta_j - 1 & 1 - \theta_j \leq U < 1 \end{cases}, \quad (8)$$

for $0 \leq \theta_j \leq 1, j = 1, \dots, m$. A theoretical foundation for minimizing variance is provided.

Queueing Simulation. In addition to Monte Carlo simulation, the application of antithetic variates has been extended to more complex system simulations, such as discrete-event simulation. As we discuss below, a major challenge in these extensions is how to control the generated random variates in a way that ensures negative correlation.

Page [3] applies antithetic variates to $M/M/1$ queueing simulation. Like Monte Carlo simulation, the basic idea is to induce negative correlation by using complementary random numbers in two consecutive runs of the simulation. Specifically, if U_i is a particular random number used for a

particular purpose (e.g., to generate the i th interarrival time or i th service time) in the first run, we use $1 - U_i$ for this same purpose in the second run. By doing so, negative correlation between the two runs is obtained and the variance of the estimator is reduced. In addition, Mitchell [4] uses antithetic variates to reduce the variance of estimates of interests in a $GI/G/1$ queueing simulation, such as waiting time and queue length. Tuffin [28] presents the application of antithetic variates to closed product-form multiclass Jackson networks and achieves improvement in simulation analysis.

Nelson [29] investigates the consequence of incorporating antithetic variates into steady-state simulation when initial-condition bias is present. He shows that antithetic variates can lead to improvement in all standard criteria under typical assumptions.

Cheng [23] gives two examples to demonstrate the use of antithetic variates for transient simulation. In the example of gas demand, the input contains an autocorrelated error sequence and the target is to calculate the average peak demand. Another example deals with average peak flow in water resource management. Both examples have a time series output. The numerical results show the significant benefit of antithetic variates in variance reduction.

Other Strategies. Instead of estimating a mean of interest, Avramidis and Wilson [7] extend antithetic variates to estimate quantile of a large-scale finite-horizon stochastic simulation. This work is based on their previous attempt [30], which integrates antithetic variates and Latin hypercube sampling into finite-horizon stochastic simulation to estimate a mean response. They provide a framework for order statistics based on quantile estimation. Antithetic variates and Latin hypercube sampling are introduced into the general framework to induce correlation. The variance reduction improvement is observed in both, single-sample quantile estimators and multiple-sample quantile estimators.

Yang and Liou [31] combine antithetic variates with another popular variance reduction technique, “control variates.” They

apply antithetic variates to generate control variates across paired replications and show that the integrated control-variate estimator is unbiased and yields a smaller variance than the conventional control-variate estimator without using antithetic variates.

LIMITATIONS

In practice, antithetic variates have two major limitations.

Efficacy is Sensitive to Problems

A basic requirement for antithetic variates is monotone response functions. This requirement can generally be satisfied in simple simulations, particularly when the inverse transform method is applied. However, it may become difficult to ensure that the response is monotone when the simulated system is complex. Cheng [22,23] shows that the method can backfire when non-monotone functions are used.

In addition, the efficiency of antithetic variates depends on how much negative correlation we can induce in the sampling. That is usually unknown beforehand. Franta [24] shows that negative correlation is highly dependent on the response functions. Cheng [22] demonstrates that a skewed distribution, such as the exponential distribution, may significantly reduce the efficacy of negative correlation.

Synchronization

When applying antithetic variates to discrete-event simulation, we should carefully synchronize the random number sequences between the two replications (runs) in a pair, in order to ensure that the outputs are negatively correlated. As presented earlier, if U_i is a particular random number used to generate an interarrival time in the first replication, $1 - U_i$ should be used to generate the interarrival time for the same customer in the second replication. The erroneous use of U and $1 - U$ can undermine the basic intent of antithetic variates, which attempt to complement a small response of U with a large response of $1 - U$, and

Table 1. Variances of the Estimators With and Without Antithetic Variates

	$f(x) = x^4$	$f(x) = \sin(0.5\pi x)$	$f(x) = \frac{e^x - 1}{e - 1}$
Without AV	7.0×10^{-4}	9.5×10^{-4}	8.3×10^{-4}
With AV	3.3×10^{-4}	7.8×10^{-5}	2.6×10^{-5}

vice versa. For simple queueing simulation, synchronization of random number sequences is not too difficult. However, it can be quite challenging when the simulated systems are complicated. Law and Kelton [12] present extensive discussions on this synchronization issue and offer several useful suggestions.

NUMERICAL EXAMPLES

We apply antithetic variates to two numerical experiments to demonstrate their effectiveness. The numerical results illustrate what can be expected from this variance reduction method.

Monte Carlo Integration

The first experiment is to evaluate a standard one-dimensional integral using Monte Carlo simulation. We want to evaluate

$$I = \int_0^1 f(x) dx.$$

Note that $I = E_U[f(x)]$, where U is uniformly distributed between 0 and 1. In Monte Carlo simulation, I is estimated using a sample mean estimator

$$\frac{1}{n} \sum_{i=1}^n f(U_i).$$

In this experiment, three functions are tested.

- (1) $f(x) = x^4$,
- (2) $f(x) = \sin(0.5\pi x)$,
- and (3) $f(x) = \frac{e^x - 1}{e - 1}$.

All of the above functions are monotone over the range we are considering (i.e., $[0, 1]$). In our numerical testing, we set $n = 100$. To estimate the variance of the estimator, we repeat 10,000 independent macroreplications.

Table 1 gives the estimated variances and shows that the variance is reduced when antithetic variates are applied.

M/G/1 Queueing Simulation

The second experiment is a single server M/G/1 queueing system, which has been discussed in many queueing theory textbooks. The interarrival time is exponentially distributed with mean 0.5 and the service time is uniformly distributed between 0 and 1. We are interested in the average waiting time in the queue and the average total time in the system for the first 100 customers.

Using antithetic variates, we conduct 10,000 independent pairs of simulation replications, making a total of 20,000 replications. In each pair, the scheme of U and $1 - U$ is used to generate the random variates. Interarrival times and service times are generated separately to ensure the synchronization. For the cases without using antithetic variates, we conduct 20,000 independent simulation replications.

Table 2. Variance of Estimators With and Without Antithetic Variates

	Var(Average Wait Time)	Var(Average System Time)
Without AV	1.34	1.36
With AV	0.57	0.57

Table 2 compares the variances obtained from these simulations. Antithetic variates significantly reduce the variances of both measurements.

APPLICATION OF OPERATIONS RESEARCH IN AMUSEMENT PARK INDUSTRY

UTKU YILDIRIM
Prorize, LLC, Atlanta,
Georgia

The amusement park is a well-known concept that describes a highly capitalized recreational environment consisting of rides, attractions, and facilities aimed toward family-oriented entertainment. Although the concept of amusement park is regarded as an American invention, the world's oldest operating amusement park, Bakken, dates back to 1583 and is located in Klampenborg, Denmark [1]. The first amusement park built in the United States, which is still in operation, is Lake Compounce in Bristol, Connecticut, which was opened in 1846 [2]. In 1955, Disneyland was introduced as a new amusement park concept that puts emphasis on several themes by combining architectural elements with costumed personnel, restaurants, and retail shops.

In the latter part of the twentieth century, theme parks have turned into one of most visited tourist destinations. Currently, there are more than 400 amusement and theme parks in the United States. According to International Association of Amusement Parks and Attractions (IAAPA), 341 million people visited amusement and theme parks in the United States in 2007 and enjoyed more than 1.5 billion rides [2]. Number of visitors and revenue increased 14% and 42%, respectively, from 1997 to 2007. In the same time frame, amusement parks and theme parks in the United States generated \$12 billion in revenues [2].

Amusement parks face increasing competition as the number of amusement parks increases and new entertainment technologies emerge. In order to attract new customers and increase repeat visits of loyal customers, theme park management needs to understand and manage customer expectations.

To that end, theme parks are collecting more information about their customers, including but not limited to ride selection, food and beverage choice, and shopping habits through the use of cutting edge technology.

Operations research is uniquely positioned to take advantage of this explosion of data. Customer behavior inside the park can be tracked and modeled with the goal of improving customer experience by reducing the wait time at attractions or supporting facilities (such as food and beverage locations). Optimizing the throughput of each facility based on the level of demand can also serve to improve operational efficiency. Lastly, pricing and revenue management techniques can be used to match customer demand segments with revenue-maximizing ticket prices.

The main purpose of this article is to provide a review of operations research models applied to the amusement park industry. Although there is a long history of research on the marketing and strategic management of theme parks, literature on applications of operations research to the amusement park industry is limited. The remainder of the article is organized as follows: First, we give an overview of simulation techniques used in the design of rides and management of the wait time associated with rides. Then we concern ourselves with the intelligent management of park resources to increase visitor satisfaction via utilization of optimization techniques. The next two sections provide an overview of revenue management tactics that can be applied to pricing tickets effectively to prevent revenue leakage and to ancillary revenue sources. Since theme park and amusement park possess similar characteristics except the concept of theming used in theme parks, these terms are used interchangeably in the article.

RIDE DESIGN AND MANAGEMENT

In a survey completed by IAAPA, rides are listed as the number one factor that attracts

visitors to theme parks, and 46% of people put the roller coasters as their favorite ride [1]. Visitors frequently attempt to take as many rides as possible to get the most enjoyment out of their park visits. Unpleasant consequences of high participation, such as long lines and high wait time, can be avoided by increasing the park capacity.

On the other hand, construction of new rides and renovation of existing rides make up the biggest portion of the theme park's capital investment. O'Brien reported that investment required for a new roller coaster is between \$3 and \$26 million dollar per ride [3]. Signature attractions such as Walt Disney World's "Mission: Space" can cost up to \$150 million [4]. The cost of increasing an existing ride's capacity can also cost millions. For example, the renovation of the "Finding Nemo" ride cost Disney nearly \$100 million [4]. Hence, a ride designed to handle maximum expected demand and avoid long lines requires a massive initial investment that may lead to wasted/idle capacity.

Theme park management can utilize Operations research models to address this problem. The first step in this process is to estimate the number of customers who will attend the park each day of the year. Since these numbers are highly variable and seasonal, a "design day" concept is utilized to summarize this information. A design day is a hypothetical day that possesses a specific characteristic defined by the targets of a theme park: i.e., forecasted demand for the design day has to be greater than forecasted demand for 95% of days across year. Finally, design day is employed to identify the optimal capacity of rides, facilities, and other supporting elements that balance the initial cost and customer experience.

Estimation of the capacity of a ride due to complex safety regulations, theme-specific requirements, and customer mix arrival pattern is challenging. The realized ride capacity is a combination of theoretical ride capacity and throughput rate of the ride. Ahmadi reports high variability of the throughput rate due to individual visitors and families who wish to ride together [5,6]. For instance, take a ride that consists of operating units, such as cars or trains, with four seats. When a

family of three is seated in an operating unit and there are no individuals in the queue to fill the last spot, throughput is 75% of the theoretical ride capacity. Ahmadi used a neural network approach to reveal the relationship between group size mixture, queue length, and throughput of the ride [7].

Desai and Hunsucker [8] proposed a simulation-based tool to estimate the capacity of a ride when one or more operational variables is altered during the design or renovation of a ride. Three existing rides are selected to develop this tool. Common operational characteristics for these rides consist of fixed ride time and capacity, loading/unloading method, and restraint checking process.

Common activities, and hence operational variables, are defined and calculated on the basis of collected data and common operational characteristics of these rides. Real-life data is organized in three groups: (i) operational variables such as loading time (time required to load customers), storage time (time required for customers to store their personal items), restraint checking time, signal ok time (time required to complete safety checks), and unloading time (time required to unload customers); (ii) ride configuration-related variables such as number of cars, number of seats per car, and ride time; (iii) customer-related variables such as arrival pattern and group sizes. In order to generalize the model, ride speed is adjusted while track length is fixed to accommodate different ride times, and triangular distribution is used to fit all random variables.

Desai and Hunsucker compared the throughput of the final model to empirical observations to validate their model. They reported that the difference between the theoretical model and the empirical results is not statistically significant. Furthermore, they designed an experiment in which they changed the parameters of each random and fixed variable to see the changes in the hourly and daily ride capacity. The results of the experiment illustrated that reduction in time spent during storage, restraint checking, and signal ok activities appeared to generate the greatest improvement in capacity. Other variables such as unloading time and number of parallel queues showed

no significant impact on capacity. Although the experiment does not consider whether the parameters are achievable in real life, it demonstrates how a decision maker can utilize this tool: (i) to estimate the increase in throughput if number of employees is increased, restraining time is reduced or extra cars are added, and (ii) to identify the optimal operating environment when demand is less than maximum capacity.

This tool can also be used in the design and analysis of new rides by using design parameters for the new ride (when available) along with operational data associated with existing rides that are similar in characteristics. Also see Tibben-Lembke [6] where closed queueing models are used rather than simulation under similar settings.

Despite all the efforts, waiting lines are unavoidable. One way to boost the customer satisfaction is to improve the quality of the time spent in the line. Theme parks often attempt to ensure that their visitors are occupied with theming, shows, or TV monitors while they are waiting. Parks also manage customers' expectation by posting estimated wait times. However, Dickson *et al.* report that wait time is still a major contributor to customer dissatisfaction [9].

Disney introduced the concept of a virtual queue, called Fastpass, at Walt Disney World. The main promise behind the concept is that visitors are assigned to a virtual location in the line and their physical attendance is not required until it is their turn in the line. As a consequence, average time spent waiting is reduced while average spending per person is increased [9].

Currently, several paid and unpaid versions of Disney's Fastpass are used in the market. The success of such an implementation depends on the number and timing of the Fastpass distribution during the day. Operations research models can be used to identify the optimal distribution that minimizes the overall wait time of visitors while considering the decision-making process of visitors (i.e., when the waiting time at the physical line is 30 min, would a visitor immediately join the line or return in an hour later?). Simulation, Kalman filtering, and queueing theory based models are proposed solve the problem

[7,10,11]. Note that virtual queues and their implementation should also be incorporated in the simulation models described earlier in this section.

PARK CAPACITY MANAGEMENT

As mentioned in the previous section, customers generally strive to maximize the number of rides they take during their visit to a theme park. One of the main factors that impacts customer flows in the park is the wait time for these rides. As the wait time for a ride increases, the customers are tempted to try other rides with shorter wait times to benefit from their limited time in the park; else they leave the park early and unsatisfied. Hence, it is crucial to understand and direct the flow of visitors in the park in order to improve service quality and customer satisfaction.

Ahmadi [5] used real data provided by a major theme park and analyzed how visitors' flow can be managed. The real data used in the analysis consists of survey data that tracks visitors' transition from one ride to another, operational data such as park opening and closing hours, ride capacities, and historical daily demand. Conceptualization of a visitor flow model consists of the destination of the visitors and the time that they spent at each destination. Once the transition probabilities are estimated via the survey answers, the remaining issue to be addressed is determining how much time the visitors are spending on rides. Intending to produce the desired result, one of the models described in the previous section can be utilized to estimate the throughput of each ride.

Ahmadi provides two different optimization models that maximize minimum-weighted number of rides given any period of time during the day [5]. The author uses a weighted average rather than the average number of rides per person per day (which is a standard metric in the industry due to fact that all rides are not equally desired). The first optimization model utilizes the actual transition probabilities and determines optimal ride capacities but ignores the flow management problem. Second optimization

model imposes actual transition probabilities when they are zero and determines the minimum ride capacity as well as guidelines for transition probabilities. The author reports substantial gains when visitor transition probabilities are influenced by the theme park management along with the ride capacity optimization.

An emerging trend in the research is the utilization of multiagent systems to model complex social structures. Kawamura *et al.* [12] implemented this concept to the theme park industry. The main requirement behind the model is utilization of some type of communication device that provides information on rides to visitors. The model is designed to control the flow of the visitors via the communication device in order to reduce congestion and increase visitor satisfaction using their preferences. Although it seems straightforward to conceptualize the problem, it is very difficult to find the optimal solution. Hence, authors developed several approximations that maximize the social welfare of the all visitors.

At this point the question is: What is required to implement a successful park capacity management solution? One key aspect is the workforce scheduling. Workforce has to be managed carefully to achieve optimal ride capacity while reducing the cost as well as considering demand variability and business requirements such as minimum customer satisfaction level. Work force of a theme park consists of part-time, seasonal, and full-time employees. To better utilize the flexibility provided by the part-time employees, number of visitors arriving every hour and how those visitors flow in the park have to be tracked. Operations research techniques, such as resource allocation models, can then be utilized to determine the number and mix of employees as well as their schedule during the day.

TICKET PRICING

As mentioned in Formica and Olsen [13], the theme park industry requires substantial capital investment not only to facilitate the design and development of the initial

establishment but also to update existing attractions and build new attractions. Compared to the upfront high fixed cost, the impact of additional customers on the variable operating cost is minimal [14]. On the other hand, the unused capacity (or unsold tickets) at the end of each day represents wasted opportunity cost. Characteristics of the theme park business, such as high fixed cost, low variable cost, seasonal demand, and the perishability of the inventory, are similar to those faced by other resemble industries (e.g., airline) in which revenue management tactics are implemented effectively. Similar to those industries, the theme park industry also seeks high utilization via price differentiation and increased repeat customers.

Differential pricing and promotional strategies are used to increase the number of visitors during the low season and to control the surplus demand during the peak season. To that end, several ticket types and bundles are introduced to accommodate different customer segments such as locals, frequent visitors, corporate affiliates, and free travelers. Introduction of annual passes is one example of how demand is stimulated during the low season by providing visitors full year access at a deeply discounted price. As one would expect, this deep discount comes with restrictions. Restrictions such as number and timing of block-out days that an annual pass holder cannot access the park determines the price tag and purchase likelihood of each annual pass.

Several annual pass packages are introduced on the basis of add-on features such as free parking and restrictions in order to segment locals and domestic visitors. On local bases, short-term marketing campaigns such as three day resident packages are frequently used to stimulate local demand during periods when demand is expected to be lower than usual. Additionally, several discount levels are made available to corporate affiliates and multiday visitors.

Although the main portion of a theme park's revenue comes from admission fees, a number of theme parks generate additional revenue through hotel reservations, merchandise, and food and beverage sales. Additional services provide an advantage and

flexibility in pricing by allowing park tickets to be bundled with hotel rooms and/or food and beverage credit to attract families.

The key problem that the decision maker faces is determining the mix of the customer segments in order to maximize the admission revenue of the theme park. Heo and Lee [14] reviewed the current ticket pricing practice in the theme park industry. Based on their findings, they proposed implementing the traditional revenue management tactics used in hospitality and travel industry such as pricing based on season, day of week, demand level, and ticket purchase time. Next, an example is provided to illustrate how pricing based on purchase time is used in the hospitality industry to separate customer segments. Airlines as well as hotels provide discounted fares if customers make reservations 14 days ahead of their actual travel dates. Unlike most business trips, leisure trips can be planned in advance; hence leisure customers readily take advantage of the low fares by reserving hotel rooms and/or plane tickets early.

Heo and Lee tested the perceived fairness of the proposed strategies and compared these with the hospitality industry where the customers are well aware of the implementation of revenue management tactics. As a result of their survey, they concluded that customers' perceived pricing based on season and day of week in the theme park industry to be fairer than a similar strategy implemented in the hospitality industry. Although most of the US theme parks currently implement flat-rate admission fees and try to achieve these authors' suggestions through seasonal promotions and discounting programs, the authors propose a more dynamic pricing strategy based on the season and the day of week. One should also note that implementation of such a strategy in the theme park industry is costly and not straightforward. The name of the customer has to be printed on the tickets and validated while accessing the parks to prevent revenue leakages that can occur due to secondary markets.

While Heo and Lee do not provide details on how the suggested strategies might be operationalized, one might surmise that a successful implementation of a disciplined

pricing strategy requires understanding and anticipation; in other words, forecasts of daily demand for each customer segment and estimates of seasonal demand–price relationship. The forecasts then have to be fed into some type of optimization or heuristic algorithm to develop ticket prices while considering business constraints.

In a manner similar to travel and hospitality industries, one solution may be to rely on an algorithm that generates a minimum ticket price (bid price) for each day and then blocks all discount levels below the minimum ticket price. At first, this solution might appear easily implementable, but the problem with implementation of this strategy is twofold: First, it is very difficult to associate a daily ticket value with an annual pass. Second, annual pass demand blocked during the peak season will impact the demand for the low season. As the number of dates that are blocked during peak season increases, the volume of the annual pass sales decreases as well as the business that annual pass holders bring during the low season.

An alternative to this approach is building a simulation model that gives the decision maker flexibility to test different parameters and strategies easily. Advantages and disadvantages of each approach can then be determined before making the final decision.

OTHER REVENUE SOURCES

Although the main portion of a theme park's revenue comes from admission fees, other sources, such as hotel reservations, merchandise, and food and beverage sales, contribute up to 70% of the revenue. Six Flags and Disney generated, respectively, 47.6% and 68% [15,16] in the same order of their revenue from admissions in 2007.

Price Waterhouse Coopers completed a research on the on-site accommodations at 29 top European theme parks [17]. Of these 29 theme parks, 14 possess on-site accommodations and 5 planned to develop on-site accommodations by the end of 2010. A former group of theme parks reported that on-site accommodations contributed to the satisfaction of customers by providing a complete

experience, and contributed to the theme park's revenue by tapping into the corporate market.

Although the degree of the theming varies across hotels, it is reported as the main element that contributed to the overall experience of the leisure visitors. Consequently, this led to an increased mean length of stay of 2.8 days for theme parks with hotels compared to 1.7 days without hotels. Theme parks also command higher room rates with the introduction of the themed rooms. On the other hand, facilities such as conference rooms and spas allowed theme parks to reach different markets and increase utilization during the low season. In addition, park tickets that are bundled with hotel rooms increased the marketing power and revenue of the theme parks.

During the high season, the real challenge is to match excess demand with the limited supply on hand. Hence, theme parks have to be clever about how to price the hotel rooms in order to maximize revenue. Rooms priced too high keep the customers away and the unused capacity will perish; rooms priced too low cause a theme park to miss revenue opportunity. This problem is a specific case of the capacity control problem that is well known in operations research. The solution of the problem is inventory assigned to each price level: in other words, price for each remaining room in the inventory. While it is known that the capacity control problem can be formulated as a dynamic programming model, this formulation is intractable in practice due to its size and complexity. As a result, various approximation methods are proposed in the literature. Decomposition and deterministic linear programming approximations are formulated and have been successfully used in practice. Lately, several stochastic programming approaches that consider demand uncertainty have been published. For further discussion see Buke *et al.* [18].

Food and beverage facilities in a theme park consist of quick-service and sit-down restaurants. Sit-down restaurants share several characteristics with the hotels, such as reservation lead time, fixed capacity, perishable inventory, and seasonal demand. Hence, the associated revenue optimization problem

can be conceptualized in a similar manner. In the case of a restaurant business, inventory is defined as the time that is required to complete a meal and output is the number of tables available for reservation in addition to price differentiation. For further discussion of this topic, see Kimes [19].

In addition to hotels and restaurants, Rajaram and Ahmadi [20] estimated that merchandise sales contribute up to 40% of theme park profits. Unlike the hotel and restaurant businesses, merchandise inventory is not perishable and location of inventory in the store is adjustable. Hence, a different revenue optimization approach must be taken. Pricing with the consideration of inventory is a well-studied topic not just in general but also specifically in the field of revenue management. Please see the literature for a general review of this topic [21]. For such problems, the kernel of the solution is in the estimation of the price–demand relation. In real-world applications, it is difficult to find a case for which demand for an item is related only to its price. Ke [22] took a more holistic approach and considered shelf space and location of each product as well. Assortment changes in a store are incorporated in to the price–demand model along with seasonality. The model aimed to identify the assortment changes (i.e., shelf space and/or location of one or more products are changed) that made positive impact on the store revenue. He utilized data from a major resort destination and reported 5% revenue improvement over historical assortment changes. Other factors that cannot be controlled by the store management such as number of visitors, weather, and competing products that contribute to the variability in demand must be identified and incorporated into the formulation in order to isolate their impact on demand.

Rajaram and Ahmadi [20] developed a survey to assess the relationship between visitor flow and store sales. In the survey, visitors were expected to enter the rides in which they participated, time that they entered the queue, time that they left the ride, and amount of money they spent after each ride. A regression in which the dependent variable is store revenue and the independent

variable is the number of visitors is developed, and the adjusted R^2 is for the resulting model is 0.96. Contrary to the aforementioned approach, authors developed a model that utilizes this relationship to maximize revenue rather than price. They built an optimization model in which revenue is modeled as weighted visitor flow where weights are calculated for each location using per-person spending at that location. As a result of the analysis, they estimated an average profit lift of 9%.

CONCLUSION

Although marketing and strategic management issues in the theme park industry have been studied extensively, documented applications of operations research in the theme park industry are limited. Simulation techniques have been used to design rides and manage the wait time associated with rides as well as controlling the flow of the visitors via multiagent systems. Optimization techniques have been used to manage park resources intelligently and increase visitor satisfaction. Finally, revenue management tactics have been applied to pricing tickets effectively to prevent revenue leakage.

Because theme parks share several characteristics with other service industries, the research on the latter one can be a good starting point to augment the literature. Although there is detailed research in the field of revenue management on hotels, merchandise, and food and beverage, it is still an open question how existing models can be improved by incorporating the characteristics of the theme park industry. Also, there is no published research completed on theme park work force scheduling problem.

INTRODUCTION

A typical research and development (R&D) or new product development () project involves up-front investment in research, which, if technically successful, will lead to a viable product, which will hopefully succeed in the market and result in a net profit. The way the investment decisions and uncertainties about their outcomes unfold in stages has made such problems fruitful areas for application of decision analysis (DA). DA methods result in improved valuation of project business plans.

Rather than evaluating plans using a risk-adjusted required rate of return to determine the value of a proposed project (i.e., the discounted cash flow approach, which tends to penalize long-term R&D due to its inherent, though diversifiable, risk), the positive cash flows in the market phase of the plan are decreased by the probability that those revenues will not be realized. In addition, DA methods take into account the fact that, if the product never reaches the market, costs associated with commercializing the product do not have to be incurred. A project that will be stopped if the product performs poorly has higher expected value (EV) than a project that will be pursued and launch its product in the market no matter what its performance is, that is, resolving

uncertainty about performance before making the product launch decision leads to an increase in the project EV. This increase in value is the expected value of information (VoI) regarding product performance.

Real options analysis (ROA) represents a concept closely related to VoI. They are based on an analogy—sometimes literal and sometimes just suggestive—to options on financial instruments, for example, the most basic financial options—put and call options on stock shares. Options are called *options* because the owner of the option actually has an option to do something or not. With put options on stocks, the owner of the option has the right to sell a stock for a fixed exercise price by some future expiration date (according to the terms of the option contract), as well as the right not to sell. If the stock is worth less than the exercise price at the expiration date, the owner of the option sells the stock for more than it is worth and gains \$1 for each \$1 by which the exercise price exceeds the stock's market price at that time. The owner of the option typically does not actually sell the stock at the exercise price, but rather settles up with the seller of the option for the gain, if it is positive. A call option allows the holder to buy at the exercise price and is of value if the actual stock is worth more than the exercise price and to do nothing otherwise. *Real options*, a term originated in the 1970s [1], came to prominence around the late 1990s. There are by now many high quality articles and books on the topic, and the references in this article are a tremendous resource for the reader interested in learning more. Real options are real situations where there are choices decision makers can make that typically limit their downside and preserve the upside by waiting before taking final actions. Practitioner-oriented articles [2,3] have described how business decisions can be mapped to financial options and to parameters for value calculation. One situation isomorphic to a financial call option, for example, is where a decision maker waits to launch a product and does

Figure 1. Option value or VoI is the integral of payoff $\times$ probability density.

so only if its performance ultimately appears promising.

Other than accounting for discount rates and for the premium paid to purchase the option, the value of the option is simply the integral of the product of probability density and value gained at different actual prices of the asset that may be obtained at the time the exercise decision must be made (Fig. 1). This is similar or equivalent (in the case of log-normal distributions) [4], to VoI in the two-act linear loss problem [5,6]. In the options theory, instantaneous returns on the underlying asset are usually assumed to be Brownian, resulting in a log-normal distribution on the asset's final price. This distribution (with a parameter for the variance of instantaneous changes) is combined with a linear loss integral and discount rate in the form of the Black–Scholes [7] option pricing formula. In DA, the probability distribution over uncertain values are typically assessed subjectively (e.g., by fitting to assessments for discrete sections of the cumulative probability curve; in particular, Gaussian distributions are sometimes used and fitted to match the first and second moments). The uncertain values assessed in DA could be the project value itself, or parameters that give information relevant to project value, and either perfect or imperfect information about these values may be available at the time of later decisions.

The situation described above is one kind of real option, which we call an *innovation*

option, where the company retains the choice of whether to launch a product until after learning the results of technical development. In the field of real options, a number of standard business decisions under uncertainty have been characterized with simple underlying microeconomic cash flow models each with its specific assumptions about which variables are random. Trigeorgis [8] classified a variety of real options, including deferring investment, defaulting during staged construction, expanding production, contracting production, shutting down and restarting operations (much of this is analyzed in rigorous economic detail in Dixit and Pindyck [9]), abandoning assets or projects, switching uses of assets, and growth of business lines.

Over time, a variety of phenomena such as corporate capabilities [10], regulations [11], and many others have been considered as real options. In DA, there has not been the same move to formally classify business application-specific decision models, and technique focuses on structuring models in any situation.

Under the right assumptions, ROA and DA frames have been shown to be equivalent [12]. Valuing a project that contains a real option should be the same as valuing it using DA, and valuing the option itself should be the same as valuing some obtainable information. The applied methods are compatible [13]. As practical tools, they have relative strengths. DA is more flexible with respect

to problem type and distribution, ROA has ready-made valuation formulas for specific problems and specific assumptions about distributions on prices (which is a plus if those assumptions reflect reality, but a limitation if not [14]). Combined approaches have been proposed [15,16] in which real options are used for parameters where public market prices are available and for risks where trading is possible, while DA assessment techniques are used to incorporate internal information for other uncertain parameters and for private risks. Furthermore, a combined approach may prove to be more transparent and in some cases allow simpler encoding of models to calculate the option value [17]. In addition, the ROA frame is more information focused rather than decision focused. With financial options, the focus is on what drives option price, for example, volatility, duration, and exercise price. Likewise, ROA focuses on understanding and, in some cases, influencing these parameters, thereby making a strategic problem out of maximizing the value added by information. DA most often identifies VoI, but tends to focus attention on understanding the drivers and distributions of the value for alternative strategies, especially those involving a more complex sequence of events and choices. ROA can include some of the structures associated with multistage decision trees in the form of compound options [18], that is, options on options, but, because these require more complex numerical calculations, their adoption has been limited.

Overall, real options and value-of-information/DA approaches can improve planning for innovation-oriented/R&D projects [19–22]. By definition, in innovative projects, new information is obtained over the course of the project, and the information is useful in setting that course. The key to realizing the benefits of these approaches is having a “smart organization” [23] oriented toward them leveraging them. Organizations may view real options and corresponding DA methods as a way of thinking (and a language), an analytical tool, or an organizational process [24]. The following sections detail, for one common type of option, how organizations can best add value to the

opportunities they obtain by understanding how their own capabilities combine with the project-based drivers of real option value and VoI.

Example

Consider a company developing a new product based on a promising technology for which it has just received a patent. The company funds the development of the product based on the hope that, after seven years with reasonable additional investment, the new product will grab a large market share and be highly profitable for a long period of time. That is the optimistic business case. But it is uncertain what it will take to make the technology commercially viable. It must be engineered to improve performance along several criteria (mass, speed of response, strength, quality, and durability). At this level, factors might be similar for all sorts of development projects ranging from a new pharmaceutical compound to clean-energy technology. Depending on the difficulty of development, the stream of investment costs, the time to market (and therefore the patent life), and the ultimate performance levels are all uncertain. Related to these factors and also uncertain are production cost and the market share the product will attain, and ultimately the profit (net present value, or NPV, of the stream of cash flows) that the entire effort will generate.

If the uncertainty is high enough, there is a good chance that even an initially attractive product could lose money—or an initially questionable product could become profitable. If at some point prospects for the product appear negative enough, efforts can be terminated to avoid incurring additional costs.

ROA and VoI can both be used capture the impact of this uncertainty, its anticipated resolution, and the impact on the probability distribution on the project value from flexibility to change in plans as the situation changes.

In a classic real options approach (explained in more detail elsewhere in this volume), we construct a binomial lattice (Fig. 2) showing the project’s projected value going up (u) or down (d) by a fixed amount in each

Figure 2. Binomial lattice for real options analysis.

period, for example, each year through the point at which the product launch decision is made. The value goes up if engineering results or market changes have been positive compared to the initial expectation, and it goes down if they are negative. At any point in the lattice, the nominal project value at time t is the result of all the up and down moves, with an adjustment for the time value of money. If the up and down moves each multiply project value by 100% plus or minus some percentage, the nominal project value is the initial value multiplied by the product of the changes. If the changes are additive, then nominal project value is the initial value plus the sum of the changes. The value at any point in time follows a binomial distribution. As the number of time periods increases, this distribution approaches log-normal (if changes are multiplicative) or normal (if changes are additive). In fact, the size of the up and down steps would typically be estimated based on a holistic estimate of the uncertainty in a single later period, and fitted to be of the right magnitude to make this work for the number of discrete time increments assumed. At any point, the project can be stopped with known costs. Using dynamic programming, we work back from the end of the lattice and calculate for each point in the lattice whether it would be best to stop at that point or to continue,

given the probability distribution on the value associated with continuing.

A DA approach to the same problem would use a decision tree with each uncertainty (time, cost, performance, market share, etc.) represented as a chance node with two or more possible outcomes and probabilities assigned for each outcome. End point values represent the NPV of the project under each path or scenario. Depending on the timing of when those uncertainties are resolved, the tree can contain decision nodes following some of the chance nodes, representing choice points at which the project may be abandoned if this leads to greater EV than continuing.

If the identified uncertainties are associated with sequential investments and are resolved essentially in sequence and at evenly spaced intervals, the decision tree closely resembles the binomial lattice. If the real option model is structured to allow for different volatilities at different times (or with respect to different drivers of uncertainty), the lattice may closely resemble a standard decision tree. Finally, if it is practical to assume that there is a single decision point in the future at which (if a flexible approach is taken) it is possible to terminate the project, then all the uncertainties prior to that point can be combined to generate a single distribution over project value, and the problem can be represented as a simple two-stage decision tree (Fig. 3). We can compare the EV of the project if it is simply continued with uncertain consequences with the EV at the first stage of the decision tree if there is a later decision point after some or all of the uncertainty is resolved. The difference in these two values can be thought of as either the value of the real option or as the VoI.

ORGANIZATIONAL CAPABILITIES AND REAL OPTIONS

Organizational capabilities are recognized as being important sources of competitive advantage for firms. Proponents of the resource-based view (RBV) perspective [25,26] argue that capabilities, whether in product development, efficient production, or market access, provide firms with

Figure 3. Two-stage decision tree.

opportunities to achieve profitable strategic positions in product markets. Over time, firms accumulate idiosyncratic combinations of capabilities that, in turn, provide unique opportunities for profitable business growth or expansion [27–31].

The options framework described above has been applied to address this concept of the firm's capabilities. Myers [1] proposed that some portion of a firm's value is based on *growth options*, yet to be realized opportunities for profitable investments. Existing research has focused on capital investment decisions [9,32] and firm or technology acquisition decisions [33–35]. Given the importance of product development as a source of new business opportunities, the application of the options framework for the management of R&D activities merits attention. While it is understood that decisions concerning R&D that create and preserve options are of value to the firm [10,36,37] and that uncertainty can actually increase a project's value [38], the relationships among the project and the firm's characteristics must also be explored as ROA seeks broader acceptance [39]. What drives option value for an organization?

During the course of translating a new technology idea into a novel commercial product or service, information regarding the technical and market feasibility of a project is revealed. The firm has the opportunity to exploit the accumulated information

about the potential net benefits of a project before committing partially or completely irreversible resources to commercialize the technology.¹ In its most simple form, an innovation project should be viewed as a sequence of two decisions: a decision to gather information about the project's prospects (experimentation stage), followed by a decision to commercialize the project (implementation stage). With this sequence of events, investment decisions for these innovation options should differ from the standard investment criteria associated with other productive assets [12,40].

The flexibility to delay making investment decisions involving commercialization activities, such as investments in specialized plant and equipment or introductory marketing campaigns, limits the appropriateness of standard investment criteria. For example, a computer software firm might initiate numerous seemingly negative NPV projects to develop new application programs given that it maintains the flexibility to abandon any individual project if prospects appear unfavorable after early development steps

¹Thus, *exploiting* an innovation option is defined as the realization of the additional EV by developing the project to a later stage. The *commercialization* of an innovation option would involve the actual production of goods or delivery of services.

Figure 4. Option frame decision model.

are conducted. Under these circumstances, the firm will find it worthwhile to finance the first steps to gather preliminary information even on those projects that initially seem least attractive.

We can combine the statistical decision theory and VoI with the concept of the firm's capabilities. While a number of authors have prescribed that R&D projects should be treated as options [37], it is common to consider only the initial project variance as the primary contributor to option value [41].² Additional project and firm-level variables are also critical in understanding how firms can best manage their investments in innovation opportunities.

A basic dyadic model illustrates how a firm can maximize the value of its innovation efforts by investing in projects that match its organizational capabilities. First, we identify characteristics that determine the potential option value of an innovation project. We

then consider the firm's capabilities that permit the firm to exploit high option value opportunities. We specifically consider the firm's *learning capability* and *abandonment capability*. An appropriate fit between project and the firm's characteristics permits the firm to appropriate the option value associated with its innovation opportunities. In addition to tactical management of individual projects, organizations should think about strategically balancing their capabilities (which themselves represent a cost necessary to exploit options) with their flow of projects.

ONE-SHOT DECISION FRAME VERSUS OPTION DECISION FRAME

In our model, we translate qualitative characteristics of the firm and the project into quantitative descriptions of the determinants of project value, from which the option value is computed (Fig. 4). In determining how the option value changes as the firm's and project's characteristics change, we identify simple, testable explanations for differences in firm's performance. This modeling approach is flexible since future extensions can quantify the impact on the firm option value of any number of different capabilities and characteristics. Since the same units are used to value projects and value organizational capabilities, our framework provides a set of tools for R&D management decisions.

²For example, Sykes and Dunham [41] suggest identifying *critical assumptions* (those factors whose uncertainty can lead to a significant negative project NPV) as a risk-management technique. They advocate setting tasks and milestones for uncertain ventures so as to achieve maximum learning (reduction in the range of uncertainty) per dollar. Our model captures this concept of maximum learning per dollar more explicitly, in a way that is consistent with Bayes' rule and with the actual loss function faced by the investor.

We consider two possible cases of a firm evaluating its decision regarding an innovation project.

Case A. First, consider a firm endowed with a project, but with no option to delay decisions about implementation until a later date. The firm can decide to go ahead with the project or to abandon the project at time t_0 only. We call this case the *one-shot decision frame*, and refer to the EV of the project to the firm here as the *intrinsic value* (V_1). In practice, such a firm would use a rule that depends on *a priori* information; the firm might, for example, approve projects that exceed a preset hurdle rate adjusted for risk. If proceeding with the project has positive EV, then V_1 is the project EV, otherwise the firm would reject the project and $V_1 = 0$.

Case B. The firm can decide to go ahead with the project or to abandon the project either at time t_0 or later at time t_f , when more information is available. We call this case the *option decision frame*, and refer to the EV of the project to the firm here as the *potential project value* (V^*_2). The firm is again assumed to maximize its EV.³ We often refer to the value of the option implicit in Case B. We call this the *potential option value*, $V^*_{(2-1)} = V^*_2 - V_1$.

In practice, we may observe that a firm treats certain investments as one-shot decisions, and others as option-type decisions. What might determine the type of behavior observed? In CASE A, the firm's observed behavior could be due to the fact that the project has no potential option value or the fact that the firm is not in a position to realize the potential option value of the project.⁴

In Case B, we can infer that there is both an option and the firm is in a position to exploit it.

Project Factors that Contribute to Option Value

Before we analyze the factors that determine the magnitude of a project's option value, we define the following terms.

x	the ultimate value of the project if it is pursued
$\mu_0 = E(x)$ at t_0	EV of the project if the firm proceeds at t_0
$\mu_f = E(x)$ at t_f	EV of the project at t_f

We assume that, at time t_0 , the ultimate value of the project, x , is normally distributed with mean μ_0 and variance U , where $U = \sigma_0^2$. At time t_f , x is normally distributed with mean μ_f and variance σ_f^2 ; this implies that some uncertainty may remain at t_f . Finally, at time t_0 , μ_f is normally distributed with mean μ_0 and variance σ_{0f}^2 (the *preposterior variance* of μ_f).

We assume normally distributed variables and a rate of information revelation (resolvability, denoted by R) for a project:

$$\sigma_0^2 = \sigma_{0f}^2 + \sigma_f^2$$

$$R = (\sigma_f^{-2} - \sigma_0^{-2}) / (t_f - t_0).$$

In order to simplify exposition, let us now assume that

$$(t_f - t_0) = 1, \text{ so } R = (\sigma_f^{-2} - \sigma_0^{-2}),$$

in other words, R is the percentage of uncertainty that can be resolved prior to the final decision point (t_f). If it is reasonable to consider R to be constant, that is, signals about true project value arrive at a constant rate,

³The firm is assumed to maximize the following: $\text{Max}\{0, E(\text{Max}[0 - \text{abandonment costs at } t_f, E(\text{project value at } t_f)])\}$. For simplicity, we have no discounting and use EV instead of the expected NPV.

⁴The firm would not be able to *exploit* the innovation option because it lacked the capability to reveal

information about the project through development efforts. For our basic model, we assume that projects or innovation options are nontransferable. The transferability of a project (project characteristic) and the capability to engage in interfirm R&D transactions (firm capability) are factors that can be added to future extensions of this model.

R can be assumed to be the upper bound on the rate of increase in precision (inverse of variance) in the estimate of the project's value (i.e., how fast can the uncertainty be resolved). It could be a project characteristic that does not change when t_0 and t_f are varied, and it depends on the characteristics of the project but not the firm. If all of the uncertainty is not resolved before the decision, then all the volatility is not actionable [42] and is captured as the option value.

We define

$$z = \mu_0 / \sigma_{0f},$$

$$V_1 = \text{Max}(\mu_0, 0).$$

The term z is the standardized value of the mean of the distribution; it serves as a useful measure of whether, in practical terms, the decision is more or less of a long-shot. Now, the upper limit on the option value (potential option value) only depends on certain project characteristics and is determined by the equation:

$$V_{(2-1)}^*(\mu_0, U, R)$$

$$= V_2^* - V_1 = E[\max(x, 0)] - \max[0, E(x)],$$

where x is normally distributed with mean μ_0 and variance $= U - [U/(1 - R)]^{-1}$, and $H(z)$ refers to the standard normal hazard function⁵ evaluated at z ; then we get

$$V_{(2-1)}^* = \sigma_{0f} H(z). \quad (1)$$

This value is increasing in σ_{0f} and decreasing in the absolute value of μ_0 , as shown in Charts 2 and 3. These relationships restate well-known results [43].

By definition, when $V_{(2-1)}^* = 0$, it makes no difference whether a firm uses the option decision frame or the one-shot decision frame. However, when $V_{(2-1)}^* > 0$, viewing the project as a one-shot decision could mean a forfeit in the EV; the potential option value component of the project would

go unrecognized. In fact, the higher the potential option value, the greater is the opportunity that may be lost.

We find that there are relationships among the different project characteristics as they relate to the potential option value. For example, increasing preposterior variance increases the option value more for projects with mean near 0 than projects with mean far from 0; and, similarly, shifting a project's mean value toward 0 increases the potential option value more for high variance projects than for low variance projects.

Equation (1) demonstrates that in our model only three project characteristics are needed to determine the potential option value, and therefore the appropriate decision frame. These are *mean* (μ_0 ranging from $-\infty$ to ∞) and *resolvable uncertainty* (σ_{0f}^2), which can be determined from the initial uncertainty ($U = \sigma_0^2$, ranging from 0 to ∞) and the *resolvability* of that uncertainty (R , ranging from 0 to 1). Mean, initial uncertainty, and resolvability are sufficient to determine the option value because R and U determine σ_f , while U and σ_f determine σ_{0f} . Specifically, the potential option value component of an innovation project is high when

- mean is close enough to 0 so that there is a reasonable likelihood that the firm would change its decision on the basis of what it learns during the experimentation stage;
- there is uncertainty to resolve and prior standard deviation must be large enough so that, under some circumstances, a firm would want to change its decision after experimentation; and
- the uncertainty must be resolvable and posterior standard deviation must be lower than prior standard deviation, or else the presence of uncertainty merely implies risk that cannot be avoided.⁶

⁵The hazard function for a probability distribution evaluated at the point z is the ratio of the probability density at z divided by the cumulative probability at z .

⁶It is possible to have two projects with identical resolvable uncertainty values, σ_{0f} , one of which arises from high values for both σ_0 and σ_f , and the second from low values for both σ_0 and σ_f . Since resolvable uncertainty rather than initial uncertainty determines option value, both projects, all

Firm's Characteristics and Option-Exploiting Capabilities

Firms in our basic model have two characteristics: *Abandonment capability* and *learning capability*. Abandonment capability is incorporated into the model simply as the cost the firm pays to abandon the project at t_f .⁷ The lower the cost to drop out of projects, the greater is the firm's abandonment capability. We denote this capability as A , and define it as the incremental cash flow⁸ to the firm when it drops out of a project. A is assumed to be negative, ranging from $-\infty$ to 0.

For learning capability from experimentation, we define L , with values that can range from 0 to 1. A value of 1 corresponds to a perfect firm that resolves all the uncertainty that can be resolved between t_o and t_f . The actual effectiveness of experimentation for a given firm on a given project is simply (RL) , that is, the product of the resolvability of the uncertainty for the project and the firm's learning capability about (resolvable) uncertainty. We shall denote the values that depend on L by using it as a superscript to distinguish those values from what they would be for

the perfect firm (potential values), which are denoted with the superscript “*”.

The firm's learning capability is a reflection of its technical expertise as well as its organizational skills at absorbing and applying new information. Making an analogy between information revelation and sampling,⁹ we define the increase in precision (σ^{-2}) between t_0 and t_f for the firm with learning capability, L , as

$$\Delta(\sigma_{of}^{-2})^L = L\Delta(\sigma_{of}^{-2})^*.$$

Since precision is additive, we can paraphrase this as

$$(\sigma_f^{-2})^L = \sigma_0^{-2} + \Delta(\sigma_{of}^{-2})^L. \quad (2)$$

Because the preposterior variance and the posterior variance must sum to the prior variance, we also have

$$(\sigma_{of}^2)^L = \sigma_0^2 - (\sigma_f^2)^L.$$

If we modify our definition of z such that

$$z(L, A) = (\mu_0 - A)/\sigma_{of}^L,$$

we find that the firm's realized project value is

$$V_2(L, A) = \sigma_{of}^L H(z(L, A)) + V_1 + A. \quad (3)$$

And therefore, the firm's *realized option value*, $V_{(2-1)}(L, A) = E[\max(x, A)] - \max[0, E(x)]$. Under our assumptions, x is normally distributed with mean μ and variance σ^2 ,

else being equal, have the same option value component. Thus, it is not enough to merely state that projects with high uncertainty should be viewed through the option frame; it is the resolvability of uncertainty, as well as the uncertainty itself that drives potential option value.

⁷In a more general model, we could also include the cost of experimentation, which would allow L to be treated directly as a choice variable that could be changed for specific projects (e.g., working staff overtime). For the purpose of discussing permanent capabilities, we assume instead that there is no incremental cost to experimentation, but rather that the effectiveness of that experimentation is a firm's characteristic. The abandonment capability parameter is specifically the additional cost incurred by abandoning the project at t_f rather than any sunk costs incurred prior to t_f .

⁸It is conceivable that a project would have a positive salvage value, but it is unlikely that this would exceed the investment in the experimental stage, which is considered lost if the project is abandoned, and capitalized if the project is pursued. A is the incremental amount written off.

⁹In sampling, adding a single sample increases precision by the inverse of the sample standard deviation squared; the latter is analogous to R in our model. The increase in precision per dollar is this value divided by the cost of a sample. A more efficient sampler would simply be one with a lower cost of sampling. This way of quantifying the real-world characteristics corresponding to R and L allows the use of statistical decision theory to describe them, thus creating a rich framework for theoretical investigation.

where $\sigma^2 = U - [(1-L)/U + LU/(1-R)]^{-1}$. Analogous to Equation (1), this is

$$V_{(2-1)}(L, A) = \sigma_{0f}^L H(z(L, A)) + A. \quad (4)$$

The realized project value and option value both depend directly on μ_0, σ_{0f}^L , and A . As a check, when the firm has perfect capabilities, the realized value is the same as the potential value (i.e., $V_{(2-1)}^* = V_{(2-1)}(1, 0)$). The comparative statics of the model, with results derived from Keisler [5], provide insights regarding the relationships among project and firm's characteristics. First, we observe that $\sigma_{0f} = (RUL)^{0.5}$ and that this is the only impact of R, U , and L on realized option value. This implies that a given percentage change in R, U , or L would have the same impact on the option value, and that the impact on σ_{0f} of an increase in L is larger when R and U are larger.

Where $V_{(2-1)}(L, A) > 0$, several facts are known about the value of sample information (analogous to option value) in a two-act linear loss problem with normal prior distributions (for details, see Raiffa and Schlaifer [43]). The impact on the option value of an increase in σ_{0f} starts low and approaches a constant slope as σ_{0f} increases. Also, the impact of a change in σ_{0f} on the realized option value is highest when z is nearest 0. The impact on z of a change in A is the same as the impact on z of the same absolute change in μ_0 , while there is an additional one to one increase in the realized option value for increases in A .

More formally (see the section titled "Appendix" for proofs):

T1: A firm's realized option value $V_{(2-1)}$ is positively related to its abandonment capability (A).

$$dV(A, \mu, z)/dA > 0.$$

T1a: The magnitude of the relationship in T1 is positively related to the project uncertainty (U) when abandonment capability is low, and negatively related when abandonment capability is high.

$$\partial^2 V(A, U)/\partial A \partial U > 0 \text{ when } A < \mu_0,$$

$$\text{and } \partial^2 V(A, U)/\partial A \partial U < 0$$

$$\text{when } \mu_0 < A.$$

T1b: The magnitude of the relationship in T1 is positively related to project resolvability (R) when abandonment capability is low, and negatively related when abandonment capability is high.

$$\partial^2 V(A, R)/\partial A \partial R > 0.$$

T1c: The magnitude of the relationship in T1 is negatively related to project mean (μ)

$$\partial^2 V(A, \mu_0)/\partial A \partial \mu_0 < 0.$$

T1d: The magnitude of the relationship in T1 is positively related to learning capability (L).

$$\partial^2 V(L, A, \sigma, \mu)/\partial A \partial L > 0$$

$$\text{when } A < \mu_0.$$

T2: A firm's realized option value is positively related to its learning capability (L).

$$dV(L, \sigma)/dL > 0.$$

T2a: The magnitude of the relationship in T2 is positively related to project uncertainty (U).

$$\partial^2 V(L, U, \sigma)/\partial L \partial U > 0.$$

T2b: The magnitude of the relationship in T2 is negatively related to project resolvability (R), if uncertainty (U) is varied to maintain a constant value for the potentially resolvable uncertainty, $U(1-R) = k$.¹⁰

$$\partial^2 V(R, U, L, \sigma)/\partial A \partial R < 0$$

$$\text{when } U(1-R) \text{ is held fixed.}$$

¹⁰As R increases, $UR = R(1-R)/k = (R-R^2)/k$, the coefficient on L in determining σ_{0f} , increases more slowly for greater values of R , diminishing to 0 as R approaches 1.

T2c: The magnitude of the relationship in T2 is negatively related to absolute value of project mean (μ).

$$\partial^2 V(L, \sigma, \mu) / \partial L \partial \mu < 0.$$

T2d: The magnitude of the relationship in T2 is positively related to the firm's abandonment capability (A).

$$\partial^2 V(L, A, \sigma, \mu) / \partial L \partial A > 0 \text{ when } A < \mu_0.$$

It is important to note that the option pricing approach for financial securities can be considered to be a special case of our model. The term μ is comparable to the strike price less the current price; however, the resolvability (R) is trivial in the case of financial assets. In the case of financial call options, the quantity about which uncertainty is resolved is the price of the underlying asset at a given point in time. Since the market updates such information over time, all parties are equally capable of assessing the market value of a share price at the appropriate date. Even though there will be uncertainty about the future value of the asset, the uncertainty of the asset at the exercise date is completely resolved.

Furthermore, the literature on option pricing for financial securities does not generally treat abandonment as a variable quantity as it is in this innovation option model.

The costs of letting a financial call option expire are trivial when compared to abandoning innovation projects, and do not vary significantly among financial market traders. A simulation of the model provided a means to examine numerical examples with varying the firm's capabilities and project characteristics. The more interesting results are described below.

Learning Capability. As Chart 1 and Chart 2 show, increasing the variance of a project does not necessarily add to its EV in an option-oriented firm. Only increasing the uncertainty that can be resolved by the firm adds value. Firms can maximize the EV by (i) selecting projects to increase the initial uncertainty while holding the final uncertainty relatively constant, and

(ii) improving their learning capability to decrease the final uncertainty.

The resolvable uncertainty facing the firm is best described by our term σ_{0f}^L , and this is what should be increased. Learning capability is particularly interesting from a strategic perspective. It is possible to have two projects with identical *theoretically resolvable uncertainty* (σ_{0f}^*) one of which arises from higher values for both σ_0 and σ_f , and the second from lower values for both σ_0 and σ_f . In the first case, the uncertainty is of a more difficult nature; the incremental value of learning capability is seen in Chart 2 as the difference between the option value at learning capability $L = 1$ and $L < 1$. Since both curves have the same value for $L = 1$ (when the firm resolves all resolvable uncertainty, regardless of the difficulty of resolution), the fact that the second curve is lower implies that learning capability is more valuable when resolvability is relatively low. In the extreme, $L = 0$ implies that the firm has no learning capability, and therefore receives no value added from the option. In fact, a firm with abandonment cost greater than 0 and for which $L = 0$ would always abandon projects with negative EV at time t_0 rather than wait to do so at t_f .

Abandonment Capability. Abandonment capability improves a firm's ability to realize option value, and it increases it the most when (i) the likelihood that the project will be abandoned after the experimentation stage is fairly high, and (ii) the project is attractive enough that there is value in going through with experimentation. The value of abandonment capability is seen in Chart 3 as the vertical gap between the two curves. In particular, as the cost of abandonment becomes arbitrarily large, no project will be pursued which has negative prior EV, since none of these projects will be abandoned at t_f . This is the case of the firm that has no abandonment capability and therefore views all project investments as one-shot decisions. As the cost of abandonment goes to 0 (perfect abandonment capability), all projects are pursued at least until t_f and abandoned then only if the implementation stage EV (μ_f) is negative. This corresponds to the firm at

Chart 1. Option value is increasing in prior standard deviation and decreasing in posterior standard deviation of project value.

Chart 2. Option value is increasing in learning capability.

the other extreme that views all projects as options.

Interestingly, the value of abandonment capability is asymmetric in terms of the project mean value. Projects with a mean value near 0 are fairly likely to be abandoned. Projects with a high mean value are unlikely to be abandoned regardless of abandonment cost, and so abandonment capability is of less value.

It is also clear from our model that abandonment capability is of higher marginal value for projects with high preposterior uncertainty. This implies that the marginal value of abandonment capability is greater when firms also have greater learning capability. For this reason, it is conceptually convenient to combine both capabilities as the *option-exploiting capability* of the firm. Figure 5 illustrates the complementary

Chart 3. Option value is asymmetric due to abandonment costs.

Figure 5. Option-exploiting capability.

nature of abandonment and learning capabilities.

Making Judgments about the Firm's Capabilities and Project Characteristics

The model described here obtains illustrative results using three parameters for project characteristics and two parameters for the firm's capabilities. In practice, a firm would use more detailed models of the decision problems before determining which projects to seek or develop and which capabilities to build. But it is useful to think at least qualitatively about how to gauge a firm at a general

level. This is easier with some representative projects in mind. For a given project, if it is possible to identify a single major downstream decision point, for example, launch or do not launch the product, then standard DA methods can be used estimate a prior probability distributions (summarized by mean and standard deviation) for ultimate NPV (after all relevant cash flows have actually occurred) as well as posterior probability distributions of NPV for each branch of the tree starting at the point at which the decision must be made, and, finally, given the probability for each branch up to the point of decision, a prior distribution on the mean of the posterior distribution.

This thought experiment could be done with the firm as it is, and then an ideal firm would know everything that is possible to know at the time of the decision—and would integrate this knowledge—but not more. An ideal learning firm could discover amounts of inputs per unit needed prior to its product launch decision, but would not know future market prices of inputs; it could know the physical characteristics of the product and how it functions in many different physical environments, but it would not know exactly how competitors and customers would react when it is introduced in a free market. Thus, much uncertainty is resolved but there is residual uncertainty. The resolvability parameter R depends on the prior standard deviation on NPV and the posterior standard deviation faced by this ideal firm at the time of its decision. An example of a project with completely resolvable uncertainty is the construction and sale of a building—at the time it is sold at a determined price, all relevant cash flows are known.

To gauge the firm's learning capability, L , results from the thought experiment above would be analyzed. The firm could consider how much its own estimate might vary from the ideal firm's estimate. If the firm could freeze time at the downstream decision point and process all the information it might have, how much could its estimate of expected net present value (ENPV) change? What is the variance of this change and how does that compare with the other sources of variance? A simpler approach might be to just pick a real firm to treat as a reference point for the ideal well-forecasting firm ($L = 1$), say the best in any closely related industry, and to pick another reference point for a poor learning firm, for example, a bulky bureaucratic firm that does not use any new information ($L = 0$), and to ask how far along the spectrum from the former to the latter one's own firm falls.

Assessment of abandonment capability would be, we believe (based on experience with DA assessments), fairly straightforward once one asks the question about a specific project and defines the costs of abandonment. The cost of abandonment is the sum of nonrecoverable project costs incurred up to

the point of abandonment and the additional costs that are incurred as a result of abandonment (e.g., disposal of equipment, severance of personnel, payments to terminate contracts). These figures would be available if the planning process requires pro forma cases for scenarios involving abandonment. In fact, firms that exercise options to abandon with any frequency ought to consider such cases simply in order to make good up-front decisions (although this is not always the case).

MATCHING PROJECT CHARACTERISTICS AND THE FIRM'S CAPABILITIES

The organizational capability to take advantage of the flexibility afforded by certain investment opportunities is without doubt of value [10,29]. It is clear from the present model, however, that the value of a firm's *option-exploiting capability* depends on the availability of innovation projects with a suitable option value. Firms operating in a technical and market environment with numerous innovation opportunities with high option value components can more easily recoup investments in abandonment capability and learning capability than firms facing lower option value projects. Figure 6 illustrates that the option decision frame is most appropriate for high option value projects owned by firms with high option-exploiting capability (quadrant 2). The one-shot decision frame is appropriate in the three remaining quadrants.

Figure 6. One-shot versus option decision frames.

It is critical to note that the need to match capabilities and opportunities is based on an assumption that projects cannot be traded in efficient markets for innovation options. A relevant market could exist if there are other firms whose abandonment capabilities, learning capabilities, or even commercialization capabilities are superior to the original owner of the project. The use of such markets would, of course, depend on the transaction costs involved with transferring innovation-related knowledge through contractual arrangements. Our model could be extended to allow for such markets by incorporating the expected price received for transferring the innovation option into our abandonment capability variable (A).

Firms in quadrants 1 and 4 have a mismatch between their capabilities and their opportunities. In quadrant 1, the firm's option-exploiting capabilities are underutilized. Such firms could seek higher option value projects or could reduce their investments in option-exploiting capabilities and move into quadrant 3. In quadrant 4, the option value of innovation projects goes unrecognized. These firms would miss opportunities for profitable investments and might benefit from investing in their option-exploiting capabilities. Firms in quadrant 4 may also have an opportunity to sell their high option value projects to other organizations with the appropriate capabilities to recognize the value of such opportunities. Thus, firms can employ both types of levers—internal capability management and project selection—to achieving an efficient resource balance that does not lead to resources wasted on projects where they are not needed, and also does not lead to losses on projects that another firm may have avoided.

Our analysis also demonstrates that the drivers of option value (e.g., mean, uncertainty, resolvability) and the drivers of option-exploiting capability (e.g., abandonment capability and learning capability) should also match each other. If a firm faces large and difficult-to-resolve uncertainty, then its investment in option-exploiting capability should be concentrated in learning capability. If it faces projects with mean

generally near 0, its investment in option-exploiting capability should be concentrated in abandonment capability. Because of the *complementarity* between abandonment capability and learning capability, firms should tend toward high levels or low levels of both capabilities.

Our simple model offers insights about the complex interrelationships that affect how successful a firm might be in extracting option value from its innovation opportunities. The primary implication of this modeling exercise is that a research manager's approach to evaluating projects should depend on both the character of the opportunity and the character of the firm in question. In particular, in high option value environments, firms that can effectively manage market exploration, technical innovation, and other organizational learning activities have a decided advantage in the race to accumulate resources and skills for competitive advantage [25,26]. Therefore, it is important for firms to know what type of option environment they operate in, and what capabilities they need to bring to exploit their particular circumstances.

An Example

The emergence of new biotechnology firms (NBFs) in the pharmaceutical industry provides a useful context to examine the implications of our analysis. Recent advances in biotechnology research have created opportunities for significant investments with significant uncertainty about prospects for success at different stages. For this reason, we might expect that pharmaceutical industry participants are endowed with numerous high option value innovation opportunities. In that case, firms can avoid significant costs associated with new drug introductions by abandoning projects if early stage research and preliminary clinical trials reveal unprofitable prospects.

This would imply that a high portion of the value of biopharmaceutical R&D opportunities resides in their option value.¹¹

¹¹Depending on the project, outcomes might be better modeled not with a normally distributed

These projects have a relatively low expected mean (especially if they must be pursued to completion) and high uncertainty that is in large measure resolved during preliminary research procedures. Do the numerous NBFs that have recently entered the industry have an advantage over incumbent pharmaceutical firms in this high option value environment?¹²

Firm's Option-exploiting Capabilities. Small entrant biotechnology firms, most started through the entrepreneurial efforts of academic researchers, have the technical strength to efficiently conduct the experimentation stage of innovation (which we believe translates to high *learning capability* because managers would quickly recognize whether the project is achieving its technical goals). NBFs would also likely exhibit high *abandonment capability*. Since researchers at these entrepreneurial firms typically have several projects "on the back burner," research attention can be quickly shifted to the most promising projects as information is gained about each project. The research function at biotechnology firms thus resembles a constantly shifting network of projects; a project that appears promising would attract researchers while a failing project would quickly lose support from internal scientists. Furthermore, an NBF's need to attract external sources of capital on an almost continual basis¹³ improves

their abandonment capability [44]; many biopharmaceutical projects are abandoned when the involved NBF fails to convince its venture capital backers or public equity market participants of the logic of additional investments in a project with disappointing preliminary results.

Large established pharmaceutical firms, with their strengths in traditional chemical-based disciplines, may be at a disadvantage in the new biology-based biopharmaceutical field [45]; this can be interpreted as a lower *learning capability* relative to NBFs. The large size of the R&D function at most pharmaceutical firms requires a formal resource allocation system that may hinder their *abandonment capabilities* [46].¹⁴ In some corporate cultures, a failed experiment is viewed as a failure of the experimenter; in such environments, abandonment can in practice be more difficult and costly. Ironically, large internal sources of capital to fund research may serve to limit a pharmaceutical firm's *abandonment capability*; unlike NBFs, which are at the mercy of the external financial markets, a large firm's internal resource allocation procedure may not respond as quickly to information revealed during the experimentation stage of development.

value, but rather as a project that can take either a high or low value. The uncertainty in this case would be expressed as the probability of receiving the high value. Whatever the firm's initial estimate of the probability—that it will receive the high value—this estimate would typically move closer to either 0 or 1 at time t_f . The fundamental arguments about the firm's capabilities and project characteristics would remain unchanged from our conclusions using the normal distribution.

¹²NBFs are very active in biopharmaceutical development. In 1991, the Pharmaceutical Manufacturers' Association reported that NBFs conducted early stage development work for approximately two-thirds of the 132 biopharmaceutical projects under development for the US drug market.

¹³For example, Sahlman [44] notes that venture capitalists, an important source of funds for NBFs,

commonly stage their investments. He observes that "By staging capital the venture capitalists preserve the right to abandon a project whose prospects look dim. The right to abandon is essential because an entrepreneur will almost never stop investing in a failing project as long as others are providing capital" (pp. 506–507).

¹⁴In fact, finance executives at Merck & Co., an established pharmaceutical firm, recognize the inadequacies of their traditional NPV analysis and have adopted option analysis for research projects [46]. It is unclear, however, how easily Merck will be able to build their option-exploiting capabilities; abandonment capability may be very difficult to develop in a large organization that spends over \$2 billion in R&D and capital expenditures per year. It is interesting to note that Merck and other pharmaceutical companies continue to enter into numerous interorganizational arrangements with NBFs to gain access to early stage research projects.

The high option-exploiting capabilities of NBFs may help explain their intensive activity in high option value biopharmaceutical projects. We hypothesize that the efficient production and marketing capabilities of established pharmaceutical firms are more appropriate for implementation (drug commercialization) activities. Thus, incumbent pharmaceutical firms might be better suited to buying the rights to drugs in latter stages of development from NBFs (when the option value component of the project diminishes), rather than developing early stage projects internally.

SUMMARY

Real options and the closely related concept of VoI in DA can improve R&D and NPD. We have considered some of the basic characteristics that determine the option value in an investment opportunity. The firm's capabilities and project characteristics whose fit drives value have precise definitions that can be quantified by borrowing established techniques from DA. While an uncertain outcome is a necessary condition for the creation of the option value, the *resolvability* of that uncertainty is also important. To capture the inherent option value of a given innovation project, however, a firm must be able to reveal information about its prospects through development efforts and have the flexibility to act in a meaningful way to acquire information. Learning capability and abandonment capability represent valuable organizational resources that can be the basis of strategic advantage.

The framework here is a starting point for addressing innovation-related capabilities,¹⁵ and it could also be applied to questions such as: How long and how intensely should

firms pursue the experimental stage before committing to implementation? Under what conditions would firms specialize in either experimentation or implementation activities? How should a firm manage interrelated projects within a portfolio? How much should firms invest in option-exploiting capabilities?

The globalization of markets and the quickening pace of technological advance have increased the volatility of many industries. In this environment, a firm's ability to add value may be determined by its recognizing real options and then utilizing the information revealed during the innovation process.

APPENDIX

This appendix provides the analytical support for the hypotheses in the main text. We use the following notation to simplify the equations in this section:

$$\sigma = (RLU)^{1/2} \quad \mu = \mu_0 - A \quad z = \mu/\sigma$$

To remove ambiguity from the partial derivatives in this section, we also use the notation

$$V(\bullet) = V_{(2-1)}(R, L, U, A, \mu, \mu_0, \sigma),$$

to define V as a function of the parameters $(\bullet)$ that are allowed to vary, with all other parameters held fixed. Finally, $f(z)$ denotes the standard unit normal probability density function evaluated at z [i.e., $f(z) = \exp(z^2/2)/(2\pi)^{1/2}$] and $G(z)$ denotes the standard unit normal right tail cumulative density function evaluated at z .

Preliminary Facts

Recalling that option value is equal to $\max(0, G(z) + f(z) - zG(z))$, we note that for $A = 0$,

$$V = \sigma \int_z^\infty x f(x) dx = \sigma(f(z) - zG(z)) \quad [43]$$

For $A \neq 0$, z is changed, and the payoff is shifted so that,

$$V = \max(0, \sigma(f(z) - zG(z)) + A).$$

¹⁵In a similar vein, Copeland and Tufano [3] essentially considers what might be called *timing* capability and calculates for a specific example the loss of option value associated with exercising at too low a market price, and the loss associated with waiting too long to even consider exercising the option, as well as how the percentage of value lost varies with the volatility of the option.

We also note for later use that $d\sigma/dR = R/2\sigma$, $d\sigma/dU = U/2\sigma$, $d\sigma/dL = L/2\sigma$, $dz/d\sigma = 1/\mu$,

$$dz/d\mu = 1/\sigma, \quad \text{and,} \quad df/dz = -zf(z).$$

The following analyses assume $V > 0$ so that the option frame is appropriate.

Proofs

T1: $dV(A, \mu, z)/dA > 0$

Proof.

$$\begin{aligned} dV(A, \mu, z)/dA &= \partial V(A, \mu, z)/\partial A \\ &\quad + \partial V(\mu, z)/\partial \mu \partial \mu / \partial A, \\ \partial V(A, \mu, z)/\partial A &= 1, \\ \partial \mu / \partial A &= -1, \\ \partial V(\mu, z)/\partial \mu &= \sigma df(z)/d\mu - \sigma dz/d\mu (G(z)) \\ &\quad + \sigma z dG(z)/d\mu \\ &= df(z)/dz - dG(z)/dz + z dG(z)/dz. \end{aligned}$$

Because $dG(z)/dz = -f(z)$, this reduces to

$$df(z)/dz + f(z) - zf(z) = -f(z),$$

and the whole derivative becomes $1 + f(z)$, which is greater than 0.

Note, for $\mu_0 > A$, the G term must be replaced by F , the left tail cumulative probability, but the first derivative of option value with respect to A is still positive.

T1a: $\partial^2 V(A, U)/\partial A \partial U > 0$ when $A < \mu_0$, and $\partial^2 V(A, U)/\partial A \partial U < 0$ when $\mu_0 < A$.

Proof.

$\partial V(A, U)/\partial A = G(z)$, that is, the probability that the project will be abandoned.

$$\begin{aligned} \partial^2 V(A, U)/\partial A \partial U &= \partial/\partial U (\partial V(A, U)/\partial A) \\ &= \partial G(z)/\partial U \\ &= (U/2\sigma) \partial G(z)/\partial \sigma \\ &= (U/2\sigma) (-f(z)) \partial z/\partial \sigma \\ &= (U/2\sigma) (-f(z)) (-(\mu_0 - A))/\sigma^2. \end{aligned}$$

Noting that $f(z) > 0$, $U > 0$ and $\sigma > 0$, we can see that the derivative is positive only when $\mu_0 - A > 0$. Of course, if the one-shot frame is appropriate, then $\partial V(A, U)/\partial A = 0$.

T1b: $\partial^2 V(A, R)/\partial A \partial R > 0$

Proof. Same as T1a, only replace U with R .

T1c: $\partial^2 V(A, \mu_0)/\partial A \partial \mu_0 < 0$

Proof.

$$\partial^2 V(A, \mu_0)/\partial A \partial \mu_0 = \partial/\partial \mu_0 (\partial V(A, \mu_0)/\partial A)$$

We know that

$$\partial V(A, \mu_0)/\partial A = G(z)$$

because the marginal value from an incremental increase in A is simply the probability that the project will be abandoned. Knowing also that an increase in μ_0 makes abandonment less likely, we get

$$\partial/\partial \mu_0 (G(z)) = \partial G(z)/\partial z \partial z/\partial \mu_0 = -f(z)/\sigma < 0$$

T1d: $\partial^2 V(L, A, \sigma, \mu)/\partial A \partial L > 0$ when $A < \mu_0$

Proof. Same as T1a only replace R with L .

T2: $dV(L, \sigma)/dL > 0$

Proof.

$$\begin{aligned} dV(L, \sigma)/dL &= \partial V(L, \sigma)/\partial L \\ &\quad + \partial V(L, \sigma)/\partial \sigma \partial \sigma / \partial L \end{aligned}$$

and

$$\partial V(L, \sigma)/\partial L = 0 \quad (\text{when } \sigma \text{ is held constant}),$$

$$\partial V(L, \sigma)/\partial \sigma > 0, \quad \text{and} \quad \partial \sigma / \partial L = RU > 0.$$

T2a: $\partial^2 V(L, U, \sigma)/\partial L \partial U > 0$

Proof.

$$\begin{aligned} \partial^2 V(L, U, \sigma)/\partial L \partial U &= \partial/\partial U (\partial V(L, U, \sigma)/\partial L) \end{aligned}$$

$$\begin{aligned}
&= \partial/\partial U \partial V(L, U, \sigma)/\partial \sigma \partial \sigma/\partial L, \\
&= \partial/\partial U (\partial V(L, U, \sigma)/\partial \sigma) \partial \sigma/\partial L \\
&\quad + \partial/\partial U (\partial \sigma/\partial L) \partial V(L, U, \sigma)/\partial \sigma \\
&= 0 + \partial/\partial \sigma \{[(f(z) - zG(z)) \\
&\quad + z^2 f(z)]L/2\sigma\} \partial \sigma/\partial U \\
&\partial \sigma/\partial U = U/2\sigma > 0, \text{ and} \\
&\partial/\partial \sigma (\partial V(L, U, \sigma)/\partial L) > 0.
\end{aligned}$$

Intuitively, increasing σ scales up the effect of L on σ , as well as decreasing the absolute value of z , which makes the option frame decision more likely to differ from the one-shot frame decision.

T2b: $\partial^2 V(R, U, L, \sigma)/\partial L \partial R < 0$ when $U(1 - R)$ is held fixed

Proof.

$$\begin{aligned}
&\partial^2 V(R, U, L, \sigma)/\partial L \partial R \\
&= \partial/\partial \sigma [\partial V(R, U, L, \sigma)/\partial L] \partial \sigma/\partial R
\end{aligned}$$

If we add the constraint $U(1 - R) = k$, that is, that total resolvable uncertainty is held constant, we find that

$$\partial \sigma/\partial R = -L^{1/2}k/(1 - R^2) < 0, \text{ and because}$$

$$\partial/\partial \sigma [\partial V(R, U, L, \sigma)/\partial L] > 0 \text{ (shown in T2a),}$$

the product of the two partial derivatives is less than 0.

T2c: $\partial^2 V(L, \sigma, \mu)/\partial L \partial \mu < 0$

Proof.

$$\begin{aligned}
&\partial^2 V(L, \sigma, \mu)/\partial L \partial \mu \\
&= \partial/\partial \mu (\partial V(L, \sigma, \mu)/\partial L) \partial \sigma/\partial \mu
\end{aligned}$$

We know that

$$\partial/\partial \mu (\partial V(L, \sigma, \mu)/\partial \sigma) < 0$$

(because a greater value of μ implies a lower probability of exercising the option

to abandon and smaller loss avoided by exercising the option), and that

$$\partial \sigma(L)/\partial L > 0,$$

so their product is also less than 0.

T2d: $\partial^2 V(L, A, \sigma, \mu)/\partial L \partial A > 0$ when $A < \mu_0$

Proof.

$$\partial^2 V(L, A, \sigma, \mu)/\partial L \partial A = \partial^2 V(L, A, \sigma, \mu)/\partial A \partial L$$

Then the proof is the same as T1a, only we replace R with L .

Observations

When $V = 0$ (even the experimentation stage is not worth pursuing), the marginal value of changes in parameters are 0 until the changes are large enough to change the decision maker from the one-shot frame to the option frame, at which point the results hold. Again, when $V = 0$, it is interesting to consider the dual question of how much of a change in project characteristic or the firm's capability does it take to shift the decision maker to the option frame. For example, the abandonment capability a firm must have in order to pursue the option frame is decreasing in the amount of uncertainty and decreasing in the project mean, while the uncertainty required to shift the decision maker to the option frame is decreasing in A . We also observe that $\partial^2 V(L)/\partial L^2$ may go from positive to negative, depending on UR ; in other words, the value of learning capability saturates at some point.

Acknowledgments

We appreciate comments and suggestions from Charles Rosa, Elizabeth Teisberg, and George Wu and others. The authors contributed equally to this article. Dr. Mang's contribution was largely completed while he was at the McCombs School of Business, University of Texas at Austin.

APPROXIMATE DYNAMIC PROGRAMMING I: MODELING

WARREN B. POWELL
Department of Operations Research
and Financial Engineering,
Princeton University, Princeton,
New Jersey

INTRODUCTION

Stochastic optimization problems pose unique challenges in how they are represented mathematically. These problems arise in a number of different communities, often in the context of problems that introduce specific computational characteristics. As a result, a number of contrasting notational styles have evolved, which complicate our ability to communicate research across communities. This is particularly problematic in the general area of multistage, stochastic optimization problems, where different communities have made significant algorithmic contributions, which have applications to a wide variety of problems.

The range of problems that can be modeled as stochastic, dynamic optimization problems is vast. Examples of major problem classes include:

- *Optimization over Stochastic Graphs.* This is a fundamental problem class that addresses the problem of managing a single entity in the presence of different forms of uncertainty with finite actions.
- *Dynamic Resource Allocation Problems.* These include scheduling people and machines, routing vehicles, managing inventories, and investing in new facilities and technologies. These problems arise in supply chain management, personnel management, health care, military operations, agriculture, and energy.

- *Demand Management.* These problems include booking strategies for airlines, hotels, hospitals, vendor-managed inventories, and incentives to control the demand for energy.
- *Management of Financial Portfolios.* These include how a portfolio should be spread over different investments to strike a balance between risk and return
- *R&D Portfolio Problems.* These include how research and development portfolios should be managed to reach specific technological goals; what investment strategy to pursue to ensure that we will meet government targets for renewable energy in 30 years. These decisions need to be made in the presence of uncertainty about prices, climate, technology, and government policy.
- *Pricing Problems.* These include how products and services should be priced to maximize total revenue.
- *Engineering Control Problems.* These include how much CO₂ should we release into the atmosphere; what time window should one commit to for providing service; at what speed should you fly your aircraft and so on.
- *Sensor Management Problems.* These include how to manage a team of technicians collecting information about the presence of disease in the population, the concentration of pollution or radiation in the atmosphere, or the concentration of pollutants in the water.

These problems are hardly exhaustive, but hint at the range of applications and types of complexities that we might encounter. In all of these problems, we face the challenge of making decisions sequentially, in that we make a decision, and then observe information that we did not know when we made the first decision. We then get to make another decision, after which we see more information. The goal is to make decisions over time that achieve some objective.

There are several ways to model these problems, and different communities have evolved modeling and algorithmic strategies to deal with specific problem classes. For example, the simulation community typically uses myopic policies (rules that do not directly consider the impact of decisions now on the future), which might depend on one or more tunable parameters. For example, a (q, Q) inventory policy orders new product if the inventory falls below q , and places an order to bring the total inventory up to Q . In this case, q and Q are tunable parameters, which can be optimized to find the best policy, indirectly taking into account the impact of decisions now on the future.

The Markov decision process (MDP) community assumes that we can represent our system as being in a state s at time t . If we choose action a , then we let $p(s'|s, a)$ be the probability that we then land in state s' . If $C(s, a)$ is the contribution (reward) we earn if we choose action a when in state s , then we can find the best action by solving Bellman's optimality equation given by

$$V(s) = \max_a (C(s, a) + \gamma \sum_{s'} p(s'|s, a) V(s')), \quad (1)$$

where γ is a discount factor. We are assuming that we are maximizing total discounted contributions over an infinite horizon. The challenge is computing the value $V(s)$ for each (discrete) state s . There are powerful algorithms for solving this problem, but they require enumerating the set of potential states. While there are many problems that can be solved with this strategy, the method breaks down when s consists of a vector of elements. This produces the well-known curse of dimensionality of dynamic programming.

Approximate dynamic programming (ADP) is both a modeling and algorithmic framework for solving stochastic optimization problems. Most of the literature has focused on the problem of approximating $V(s)$ to overcome the problem of multidimensional state variables. In addition to the problem of multidimensional state variables, there are many problems with multidimensional random variables, and multidimensional

decision variables (most commonly referred to as *actions* in the dynamic programming community, or *controls* in the engineering literature). These three challenges make up what have been called the *three curses of dimensionality*.

It is important in any presentation on dynamic programming to acknowledge the different communities that have contributed to the field. The challenge of making good decisions over time in the presence of uncertainty arises in a number of fields, and as a result it is not surprising to see similar ideas being developed under different notational systems and different vocabularies. These communities include:

- *Discrete MDPs*. This covers research in computer science as well as the MDP community in operations research. These problems are typically characterized by discrete states (with possibly many states), and discrete actions, but typically not very many actions.
- *Control Theory*. These communities include engineering in the physical sciences and economics. Problems are often modeled in continuous time, with decision variables (controls) that are typically continuous and low-dimensional (e.g., one to a dozen dimensions). Randomness often arises in the form of measurement noise.
- *Stochastic Programming*. This community deals with vector-valued (and often high-dimensional) decision vectors and general forms of uncertainty, which are represented using scenario trees. This community typically does not use Bellman's optimality equation as an algorithmic device.
- *Simulation Optimization*. The simulation community generally uses myopic policies to make decisions over time, but these policies may be governed by a vector of tunable parameters that can be optimized. This community also does not use Bellman's equation to guide decisions, but there are close parallels between the problem of optimizing policies in simulation, and policy optimization in dynamic programming.

Although the roots of ADP can be traced to early work by Bellman [1], the ideas evolved independently within different fields, notably the early work on training computers to play games [2,3] and the work in control theory [4–6]. The work in computer science evolved under the name “reinforcement learning,” where the first published use of this term is in Ref. 7 (the roots of this work can be found in Minsky’s Ph.D. dissertation [8]; see also Ref. 9). Reinforcement learning as a field did not really emerge until the 1980s with Barto *et al.* [10], followed by numerous contributions by Sutton and Barto through the 1980s, eventually leading to their ground breaking book [11]. Work in control theory took place under a variety of names, including reinforcement learning, adaptive dynamic programming and (later) ADP, with important early contributions by Paul Werbos [4–6,12]. The seminal book by Bertsekas and Tsitsiklis [13] introduced the term *neurodynamic programming*, but it appears that this term is being replaced with ADP (see for example, Ref. 14, Chapter 6).

While ADP in its various forms really accelerated in the 1990s in computer science and control theory, there was relatively little attention given to ADP in the operations research community until after 2000. One of the earliest papers in the operations research literature to explicitly use the term *approximate dynamic programming* is Ref. 15, although others have done similar work under different names such as *adaptive dynamic programming* [16–18]. Methods for handling vector-valued decision variables in a formal way using the language of dynamic programming appear to have emerged quite late (see in particular, Ref. 19), although other authors have used specialized techniques from math programming to solve multistage stochastic optimization problems. Pereira and Pinto [20] in particular, introduce the idea of using Benders cuts to overcome the curse of dimensionality in dynamic programming (see also Ref. 21, Chapter 11). This idea has enjoyed a substantial literature (see Birge and Louveaux [22], Higle and Sen [23]), but these have evolved independently of the ADP community.

From this discussion, we feel that any discussion of ADP has to acknowledge the fundamental contributions made within computer science (under the umbrella of reinforcement learning) and control theory. The one dimension that these communities largely ignored was problems that involved high-dimensional decision variables, which are common in operations research. The first book to bridge the gap with mainstream operations research in a thorough way did not appear until Powell [21].

MODELING A STOCHASTIC OPTIMIZATION PROBLEM

Before we can solve a problem, we have to model it. In this section, we review the five fundamental dimensions of a stochastic, dynamic systems, which include: (i) states, (ii) actions/decisions/controls, (iii) exogenous information/random variables, (iv) transition function, and (v) objective function. We use this presentation to review the different notational systems used by different communities.

States

It is with some surprise that we have found that few authors attempt to actually define a state variable. Powell [21] offers the following definition:

Definition 2.1. A **state variable** is the minimally dimensioned function of history that is necessary and sufficient to compute the decision function, the transition function, and the contribution function.

This definition is familiar to researchers in control theory (in particular, in electrical engineering). The modifier “minimally dimensioned” is intended to restrict the state variable to all the information needed, but only the information needed, so that it is as compact as possible.

The MDP framework, used in both computer science and operations research, uses s for state, or S_t for the random variable describing the state at time t . Control theorists use x . Most applications involve

modeling a physical state (the status of a piece of equipment, the amount of products in different inventories), but many problems require modeling an information state (information used to make a decision), and for some applications, a belief state (when we are unsure about the actual state of our system).

Decisions/Actions/Controls

We might refer to action a (MDPs), control u or decision x . While it is easy to view these as different variable names for the same quantity, it is also the case that these communities tend to work on different types of problems. Although exceptions abound, in most cases a refers to a relatively small (that is, easy to enumerate) set of discrete actions; the control u is typically a low-dimensional (e.g., 1–10) continuous vector (density, pressure, velocity, acceleration, price); and the decision vector x in operations research is often very high-dimensional, with hundreds to tens of thousands of dimensions.

We defer until later the problem of determining how to make a decision, other than to say that we will ultimately look for a *policy* π , which is a rule (or function) for determining a decision using the information in the state variable S_t . We might use π to represent this rule, or a function $A^\pi(S_t)$ to determine the action a_t or $X^\pi(S_t)$ to determine the decision x_t . We let Π be the set of all possible policies (or functions), which takes on different meanings as we give a policy structure in a specific setting.

Exogenous Information

We are typically interested in problems that are driven by some sort of exogenous information process. This might come from a physical system (observed prices or rainfall) or a probability distribution. These are modeled as random variables, but there is an important distinction between whether the underlying probability distribution is known or not.

While communities have standard notation for states and actions, we are unaware of any standard notation for exogenous information. The MDP community typically does not explicitly model exogenous information,

preferring the more compact representation of the one-step transition function $p(s'|s, a)$. In control theory, we often see w_t for random information. Given the preference of the applied probability community to use capital letters for random variables, we use W_t as our generic notation for random information.

A separate modeling issue for discrete-time models is the modeling of time. In a continuous-time model, W_t would represent information arriving between t and $t + dt$. For discrete-time problems, there are many authors who would let W_t be new information (about rainfall, changes in prices, new demands) arriving between t and $t + 1$, but this means that at time t , W_t is random. We prefer the convention, widely used in the applied probability community, that W_t represents information arriving between $t - 1$ and t . With this convention, any variable indexed by t is known at time t .

We let ω represent a sample path $(W_1, W_2, \dots)$ where $\omega \in \Omega$. To finish the formalism, we let $\mathcal{F}$ be the sigma-algebra on Ω (the set of events), and let $\mathcal{P}$ be a probability measure on $(\Omega, \mathcal{F})$. Finally, because information evolves, over time, we let $\mathcal{F}_t$ be the sigma-algebra generated by the variables $(W_1, \dots, W_t)$, which implies that $\mathcal{F}_t \subseteq \mathcal{F}_{t+1}$ is a sequence of filtrations. We can use this notation to express the dependence of state variables and decisions on information that has arrived prior to time t .

There are instances where it is useful to provide an explicit model of the history. For this purpose, we can define

$$\begin{aligned} H_t &= \text{The history of the process,} \\ &\quad \text{consisting of all the information} \\ &\quad \text{known through time} \\ &\quad t, = (W_1, W_2, \dots, W_t), \\ \mathcal{H}_t &= \text{The set of all possible histories} \\ &\quad \text{through time } t, \{H_t(\omega) | \omega \in \Omega\}, \\ h_t &= \text{A sample realization of a history,} \\ &\quad H_t(\omega), \\ \Omega(h_t) &= \{\omega \in \Omega | H_t(\omega) = h_t\}. \end{aligned}$$

In the stochastic programming community, it is common to model uncertainty through scenario trees, which represent the branching of outcomes as new information becomes available. Imagine all the outcomes

$\omega \in \Omega(h_t)$, which correspond to a common history h_t at time t . We can model this juncture as a node $n \in \mathcal{N}$, where each node n captures a particular history at a point in time. All the outcomes that meet at node n follow a common path (corresponding to the history h_t). Rather than use an explicit model of time, the modeling of scenario trees typically refers to predecessor nodes and successor nodes. A decision made at node n of the tree has to depend on the information up to that juncture. This representation does not use the concept of a state variable, where outcomes with different histories can lead to the same state.

It is interesting to contrast the use of scenario trees in stochastic programming with state variables in dynamic programming. A node in a scenario tree corresponds to an entire history. Not surprisingly, scenario trees grow exponentially in size as the number of time periods increases. For this reason, there is a literature addressing the problem of generating scenario trees, which capture desirable properties with a minimum number of outcomes [24–26]. It is perhaps interesting that the stochastic programming community, which focuses primarily on problems with multidimensional decisions x_t , views dynamic programming as a method that is limited to small problems (due to the “curse of dimensionality”) when in fact scenario trees suffer from a similar curse of dimensionality when representing exogenous information processes.

In practice, scenario trees are used most often when the history of a process plays an important role. Although the history can be easily added to a state variable, the result is an extremely large state space where there may be a unique state for each sample path (which shares a common history). We note that scenario trees are generated prior to solving the problem, which means that this method of modeling uncertainty is unable to handle problems where the exogenous outcome depends on a prior decision. For example, we may be modeling random prices to determine the value of an asset. If we sell more, the prices may drop. For such problems, we cannot generate scenario trees in advance.

The Transition Function

There are different styles for modeling how the system evolves over time. The convention in operations research is to use systems of equations, such as

$$A_t x_t + B_{t-1} x_{t-1} = b_t. \quad (2)$$

In the MDP community, the evolution of the system is described using the one-step transition matrix $p(s'|s, a)$.

In the control theory community, it is common to define a function that maps state, action, new information to new state, as in

$$S_{t+1} = S^M(S_t, a_t, W_{t+1}).$$

The function $S^M(\cdot)$ goes under many names such as *plant model* (literally, the model of a physical production plant), *plant equation*, *law of motion*, *transfer function*, *system dynamics*, *system model*, *transition law*, and *transition function*. We use “transition function,” but adopt notation that captures the widely used term *system model*. Transition functions are typically straightforward to specify (with exceptions as we note below), although in many engineering applications, they can be quite complex. For this reason, it is common practice to specify the existence of a transition function when modeling a problem without actually writing out the details. This contrasts sharply with writing out systems of linear equations such as Equation (2), where all the details of the transition are fully specified.

It is often overlooked that the one-step transition matrix is actually an expectation, since it can be derived directly from the transition function as follows:

$$\begin{aligned} \mathbb{P}(s'|s, a) &= \mathbb{E}\{\mathbf{1}_{\{s'=S^M(s, a, W_{t+1})\}} | S_t = s\} \\ &= \sum_{\omega_{t+1} \in \Omega_{t+1}} \mathbb{P}(W_{t+1} = \omega_{t+1}) \\ &\quad \times \mathbf{1}_{\{s'=S^M(s, a, W_{t+1})\}}. \end{aligned}$$

The problem with one-step transition matrices is that they tend to be extremely large, measuring the number of states times the number of states times the number of

actions. One-step transition matrices have enjoyed a rich history in the literature for MDPs, where they have facilitated an elegant theory. But in practice, it is only an extremely narrow class of problems where they can actually be computed.

Objective Function

The final dimension of our model is the objective function. We might minimize a cost or maximize a contribution (or reward). Assuming that we are maximizing, we define

$C(S_t, a_t)$ = Contribution received for being in state S_t and taking action a_t .

The contribution might be a random variable, which we would then write as $C(S_t, a_t, W_{t+1})$. In many applications, we observe the next state S_{t+1} but do not explicitly observe W_{t+1} , in which case we may write the contribution as $C(S_t, a_t, S_{t+1})$. In either case, $C(S_t, a_t)$ would be the expected contribution. The most common assumption is that we are maximizing total discounted rewards over a finite or infinite horizon, which we would write as

$$F^\pi(S_0) = \mathbb{E} \left\{ \sum_{t=0}^T \gamma^t C(S_t, A^\pi(S_t)) \right\}, \quad (3)$$

where γ is a discount factor. It is very common to let $T \rightarrow \infty$ and solve for a steady-state policy, but for other problems, solving undiscounted, finite-horizon problems is the standard model. We note that we are assuming that our objective function can be written in the form of additive rewards.

We let $A^\pi(S_t)$ be a function, parameterized in some way by $\pi \in \Pi$, that determines the action a_t given the information in the state S_t . Our goal is to find the best policy, which means solving

$$\max_{\pi \in \Pi} \mathbb{E} \left\{ \sum_{t=0}^T \gamma^t C(S_t, A^\pi(S_t)) \right\}. \quad (4)$$

Solving this optimization problem directly, even for very simple problems, is computationally intractable. The breakthrough of dynamic programming is realizing

that this problem can be solved using Bellman's optimality equation (see Ref. 27 for a modern and thorough discussion of this field), which can be written as

$$V_t(S_t) = \max_a (C(S_t, a) + \gamma \sum_{s'} P(s'|S_t, a) V_{t+1}(s')), \quad (5)$$

$$= \max_a (C(S_t, a) + \gamma \mathbb{E}\{V_{t+1}(S_{t+1})|S_t\}), \quad (6)$$

where $S_{t+1} = S^M(S_t, a, W_{t+1})$. For steady-state problems, we let $V_t(S) = V_{t+1}(S) = V(S)$. If states are discrete (and there are not too many of them), the number of actions is not too large, and the expectation is easy to compute, then Equation (5) or (6) can be used to find the best action a for each state S , which gives us a lookup table representation of a policy. Unfortunately, only a small number of toy problems meet these criteria, which is what leads us to the field of ADP.

MAJOR PROBLEM CLASSES

ADP arises because of the computational difficulties in solving Bellman's equation. Now that we have our modeling framework in place, we can discuss more precisely about the nature of these complexities.

There are three computational challenges that arise in the solution of Bellman's equation:

1. Finding the value function $V(S)$ (or $V_t(S_t)$ for finite-horizon problems).
2. Computing the expectation.
3. Finding the best action.

The nature of these challenges arises from the characteristics of three variables: the state variable S_t , the exogenous information variable W_t , and the action a_t /control u_t /decision x_t .

State variables can typically be divided between whether the state space is (i) discrete and easy to enumerate (up to thousands of states, but not millions), (ii) scalar and continuous, or (iii) a vector (whether it is discrete

or continuous). Often, cases (ii) and (iii) are equivalent from a computational perspective, but scalar, continuous variables tend to offer special structure. The third case spans discrete vectors (how many cars of each model are in inventory), continuous vectors (how much money is invested in each investment choice), vectors of categorical attributes, and of course a mixture of all of these. There are many applications where the state variable is complicated by the need to retain some portion of the history of the process. When this happens, a common modeling strategy is to use scenario trees.

For the random vector W_t , we are primarily interested in whether we can compute the expectation in Bellman's equation. Vectors of random variables may be easy if they are independent, and of course the problem is easiest when there are no autocorrelations linking observations over time. It is possible that the random information is simple, but we do not know the probability distribution. For example, the random variable may simply capture whether a person accepts a bid in an auction or not; the random variable is Bernoulli, but we do not know the probability distribution describing the person's behavior. It is also important to separate problems where W_t is independent of all prior history; problems where W_t depends on the state S_t , and problems where W_t depends on both the state S_t and action x_t .

For decisions, there may be a small number of discrete actions a , a single scalar decision, low-dimensional continuous vectors u , or high-dimensional continuous or discrete vectors x . For vector-valued actions, we typically need some sort of search algorithm such as a linear program or genetic algorithm to find x . The choice of algorithmic search strategy can have an impact on how we represent future events when making a decision.

The default way to handle any dynamic program is to discretize all the states and actions, and assume that we can compute expectations. When the number of states and actions is small enough to enumerate when discretized, and when we can compute expectations, we typically can solve Bellman's equation (Eq. 1) exactly using classical techniques [27]. If the state variable is a vector,

discretizing it can produce an exponentially large number of states, a problem that is routinely referred to as the *curse of dimensionality* (a term coined by Bellman). The same problem arises with the information variable W and the action $a/u/x$. However, there are problems where W may be continuous, but where the expectation is still easy. There are other problems where the information may be fairly simple (e.g., the behavior of an opponent or the price of a stock), but where we do not know the distribution, and therefore, we cannot compute the expectation. Finally, there are problems where the decision variable is a vector, which makes it impossible to enumerate all the actions. When all three of these problems arise (vector-valued states, uncomputable expectation, and vector-valued decisions), we say that we have three curses of dimensionality.

TYPES OF POLICIES

The challenge of dynamic programming is finding a good rule for making decisions given a state. We refer to this rule as a *policy*. Policies come in a number of forms, and the precise form can play a major role in the design of an algorithm for finding a good policy. A policy is often denoted as π , which is a generic mapping from a state to an action. It is convenient to emphasize that this is really a function. If the action is a , we might designate the function as $A^\pi(S)$ for the action that we would take if we are in state S . If your action is x , we could use $X^\pi(S)$. We design our space of possible policies using $\pi \in \Pi$, but what this means computationally is very dependent on the nature of the policy (or decision function). Examples of policies include:

1. *Lookup Tables.* For a discrete state s , $A^\pi(s)$ is the discrete action we should take. If there are 100 states and 10 actions per state, our policy space would have 1000 parameters.
2. *Parameterized Myopic Policies.* Let S_t be the amount of inventory on hand at time t . A reorder policy might be to order $X^\pi(S_t) = Q - S_t$ if $S_t < q$ and 0

otherwise. This policy is parameterized by q and Q , so we might say $\pi = (q, Q)$. The set of all possible policies is the set of potential values for q and Q .

3. *Statistical Models.* When controlling energy commitments from a wind farm, let W_t be the wind speed. We have to decide how much energy to commit to the grid, which we might model using $x_t = \theta_0 + \theta_1 W_t + \theta_2 W_t^2 + \theta_3 W_t^3$. This regression function is a policy parameterized by $(\theta_0, \theta_1, \theta_2, \theta_3)$. Within this category, we would include training a neural network to represent a policy, a strategy that is common in the neural network community (see Ref. 28, Chapter 12).
4. *Myopic Optimization Models.* Let $C(S_t, x_t)$ be the contribution earned by using decision x when we are in state S . An example might be a resource allocation problem where we are allocating people, products or machinery to different tasks or demands. S_t captures the current status of our resources and tasks, and x_t is our vector of decisions of who gets assigned to what. We could solve our problem using

$$X^\pi(S_t) = \arg \max_{x \in \mathcal{X}} C(S_t, x).$$

This means finding the best assignment of resources now, without regard to the impact of these decisions on the future. We note that solving this problem may involve using a solver for linear, nonlinear, or integer programs, or using a heuristic search algorithm such as tabu search or genetic algorithms.

5. *Tree Search.* For problems with typically small action spaces, it is possible to estimate the value of a particular state by enumerating all the actions and subsequent states that result from reaching a particular state. These methods are widely used in the design of algorithms for playing games (see Ref. 29).
6. *Roll-Out Heuristics.* When it is not possible to enumerate all the actions out of a state (as in tree search), it may

be the case that we have access to a reasonable (but suboptimal) policy. A roll-out heuristic evaluates the value of a particular state s' (that we might reach from state s using a potential action a) by following this policy starting from s' for a specified number of iterations. The value of this simulated sample path can be used to approximate the value of reaching state s' . See Ref. 30 for a more in-depth discussion of this strategy.

7. *Rolling Horizon Policies (Deterministic).* We could also optimize over a planning horizon T using

$$U^\pi(S_t) = \arg \max_{u \in \mathcal{U}} \sum_{t'=t}^{t+T} C(S_{t'}, u_{t'}),$$

where point forecasts are used to make decisions over the horizon $t, \dots, t+T$. We only use u_t as our decision to implement right now. This strategy is also known as a *receding horizon policy*, or, in the control theory community, *model-predictive control*. Rolling horizon policies are mathematically equivalent to tree search, but are normally written in the context of multidimensional decision/control problems where a solver of some sort is used to solve the optimization problem.

8. *Rolling Horizon Policies (Stochastic).* Classical rolling horizon policies use a point forecast of the future, but it is possible to use a stochastic model, which captures uncertainty in potential future events. This strategy is most popular in the stochastic programming community, which represents possible outcomes of future events as scenarios in a set Ω_t . An outcome $\omega \in \Omega_t$ would be viewed as a set of potential events over time periods $t, t+1, \dots, t+T$.

$$\begin{aligned} X^\pi(S_t) = \arg \max_{x_t \in \mathcal{X}} & C(S_t, x_t) \\ & + \sum_{\omega \in \Omega_t} p(\omega) \\ & \times \sum_{t'=t+1}^{t+T} C(S_{t'}(\omega), x_{t'}(\omega)). \end{aligned}$$

These problems have to be solved subject to constraints (known as *nonanticipativity constraints* in the stochastic programming community), which ensure that a decision x'_t does not see information that becomes available at time periods later than t' .

9. *Value Function Approximations.* In this strategy, we use an approximation of the value function in Bellman's equation, where we would make a decision by solving

$$A^\pi(S_t) = \arg \max_a (C(S_t, a) + \gamma \mathbb{E}[\bar{V}_{t+1}(S^M_t(S_t, a, W_{t+1})) | S_t]), \quad (7)$$

where $\bar{V}(S)$ is an approximation of the value of being in state S . The space of policies is the space of potential value function approximations.

Lookup tables are easy to visualize but require enumerating states and actions, so this is precisely the type of policy that is sensitive to curse of dimensionality issues. Finding the best parameters in a parameterized policy is a topic that has been widely studied in the literature known as simulation optimization [31–34] where the techniques of stochastic search are used [35]. Rolling horizon policies have been viewed as a form of ADP (see Ref. 36 for a discussion of the relationship between ADP and model-predictive control), since they are in the same mathematical class as tree search algorithms and roll-out policies [30].

ADP arises primarily when we are looking for a value function approximation that determines a decision using equations such as Equation (7). However, finding the best statistical model (policies of type 3 above) is also an important strategy in the ADP literature, where it is referred to as *approximate policy optimization*. This is particularly common in the control theory community where a policy is a neural network (literally, a statistical model). It can be argued that finding the best regression function (type 3) and finding the best value function (type 9) are mathematically equivalent (both produce functions

that are determined by regression methods), but the computational issues are different. The problem of finding the best approximation of a policy is closest to policy iteration of dynamic programming, while finding the best value function approximation is closest to value iteration.

MODEL-FREE DYNAMIC PROGRAMMING

A topic that is very popular in computer science (in the reinforcement learning community) and engineering is a problem class that is referred to as *model free*. These applications arise in the context of more complex applications, but the term *model free* can take on different meanings in different settings. In a nutshell, model-free dynamic programming arises when we cannot compute

$$a_t^n = \max_a (C(S_t^n, a) + \gamma \mathbb{E} V_{t+1}(S^M_t(S_t^n, a_t, W_{t+1}(\omega^n))). \quad (8)$$

There are three calculations implied in the solution of Equation (8):

1. computing $S_{t+1}^n = S^M(S_t^n, a_t, W_{t+1}(\omega^n))$ using the transition function,
2. computing the expectation, and
3. computing the contribution function $C(S_t^n, a)$.

There are many applications where we cannot compute some combination of these calculations. The most common are problems where we do not have an explicit transition function. Given the fact that many refer to this as the model, the lack of a model (transition function) resulted in algorithmic strategies, which address this dimension as model-free dynamic programming. These techniques apply equally to problems where we cannot compute the expectation, which can easily arise because observations are from an exogenous process where we do not know the underlying probability distribution. There are also problems where we do not have an explicit contribution (or reward or utility) function. These can arise when we are trying to mimic a human making

decisions, where we do not know the precise utility function that guides the human.

The reinforcement learning community often requires a model-free framework since this community is frequently working on problems that involve mimicking human behavior. Model-free dynamic programming is so common, in fact, that authors feel that they have to explicitly state when an algorithm is model-based. The control theory community often encounters model-free applications when the physics of a particular problem (e.g., modeling a chemical plant) is simply too complex to represent as a mathematical model.

CLOSING REMARKS

The goal of this article was to outline a general strategy for modeling stochastic, dynamic problems. Designing effective policies is a difficult challenge, which requires taking advantage of the nature of a particular problem. ADP offers very general algorithmic framework for solving these problems. An introduction to this approach is given in Ref. 37.

APPROXIMATE DYNAMIC PROGRAMMING—II: ALGORITHMS

WARREN B. POWELL

and Financial Engineering,
Princeton University, Princeton,
New Jersey

INTRODUCTION

Approximate dynamic programming (ADP) represents a powerful modeling and algorithmic strategy that can address a wide range of optimization problems that involve making decisions sequentially in the presence of different types of uncertainty. A short list of applications, which illustrate different problem classes, include the following:

- *Option Pricing.* An American option allows us to buy or sell an asset at any time up to a specified time, where we make money when the price goes under or over (respectively) a set strike price. Valuing the option requires finding an optimal policy for determining when to exercise the option.
- *Playing Games.* Computer algorithms have been designed to play backgammon, bridge, chess, and recently, the Chinese game of Go.
- *Controlling a Device.* This might be a robot or unmanned aerial vehicle, but there is a need for autonomous devices to manage themselves for tasks ranging from vacuuming the floor to collecting information about terrorists.
- *Storage of Continuous Resources.* Managing the cash balance for a mutual fund or the amount of water in a reservoir used for a hydroelectric dam requires managing a continuous resource over time in the presence of stochastic information on parameters such as prices and rainfall.

- *Asset Acquisition.* We often have to acquire physical and financial assets over time under different sources of uncertainty about availability, demands, and prices.
- *Resource Allocation.* Whether we are managing blood inventories, financial portfolios, or fleets of vehicles, we often have to move, transform, clean, and repair resources to meet various needs under uncertainty about demands and prices.
- *R&D Portfolio Optimization.* The Department of Energy has to determine how to allocate government funds to advance the science of energy generation, transmission, and storage. These decisions have to be made over time in the presence of uncertain changes in technology and commodity prices.

These problems range from relatively low-dimensional applications to very high-dimensional industrial problems, but all share the property of making decisions over time under different types of uncertainty. In Ref. 1, a modeling framework is described, which breaks a problem into five components.

- *State.* S_t (or x_t in the control theory community), capturing all the information we need at time t to make a decision and model the evolution of the system in future.
- *Action/Decision/Control.* Depending on the community, these will be modeled as a , x , or u . Decisions are made using a decision function or policy. If we are using action a , we represent the decision function using $A^\pi(S_t)$, where $\pi \in \Pi$ is a family of policies (or functions). If our action is x , we use $X^\pi(S_t)$. We use a if our problem has a small number of discrete actions. We use x when the decision might be a vector (of discrete or continuous elements).
- *Exogenous Information.* Lacking standard notation, we let W_t be the family

of random variables that represent new information that first becomes known by time t .

- *Transition Function.* Also known as the *system model* (or just *model*), this function is denoted by $S^M(\cdot)$, and is used to express the evolution of the state variable, as in $S_{t+1} = S^M(S_t, x_t, W_{t+1})$.
- *Objective Function.* Let $C(S_t, x_t)$ be the contribution (if we are maximizing) received when in state S_t if we take action x_t . Our objective is to find a decision function (policy) that solves

$$\max_{\pi \in \Pi} \mathbb{E} \left\{ \sum_{t=0}^T \gamma^t C(S_t, X^\pi(S_t)) \right\}. \quad (1)$$

We encourage readers to review Ref. 1 (in this volume) or Chapter 5 in Ref. 2, available at <http://www.castlelab.princeton.edu/adp.htm>, before attempting to design an algorithmic strategy. For the remainder of this article, we assume that the reader is familiar with the modeling behind the objective function in Equation (1), and in particular the range of policies that can be used to provide solutions. In this article, we assume that we would like to find a good policy by using Bellman's equation as a starting point, which we may write in either of two ways:

$$\begin{aligned} V_t(S_t) &= \max_a (C(S_t, a) \\ &\quad + \gamma \sum_{s'} p(s'|S_t, a) V_{t+1}(s')), \quad (2) \\ &= \max_a (C(S_t, a) + \gamma \mathbb{E}\{V_{t+1}(S_{t+1})|S_t\}), \quad (3) \end{aligned}$$

where $V_t(S_t)$ is the value of being in state S_t and following an optimal policy from t until the end of the planning horizon (which may be infinite). The control theory community replaces $V_t(S_t)$ with $J_t(S_t)$, which is referred to as the cost-to-go function. If we are solving a problem in steady state, $V_t(S_t)$ would be replaced with $V(S)$.

If we have a small number of discrete states and actions, we can find the value function $V_t(S_t)$ using the classical techniques of value iteration and policy iteration [3]. Many

practical problems, however, suffer from one or more of the three curses of dimensionality: (i) vector-valued (and possibly continuous) state variables, (ii) random variables W_t for which we may not be able to compute the expectation, and (iii) decisions (typically denoted by x_t or u_t), which may be discrete or continuous vectors, requiring some sort of solver (linear, nonlinear, or integer programming) or specialized algorithmic strategy.

The field of ADP has historically focused on the problem of multidimensional state variables, which prevent us from calculating $V_t(s)$ for each discrete state s . In our presentation, we make an effort to cover this literature, but we also show how we can overcome the other two curses using a device known as the *postdecision state variable*. However, a short article such as this is simply unable to present the vast range of algorithmic strategies in any detail. For this, we recommend for additional reading, the following: Ref. 4, especially for students interested in obtaining thorough theoretical foundations; Ref. 5 for a presentation from the perspective of the reinforcement learning (RL) community; Ref. 2 for a presentation that puts more emphasis on modeling, and more from the perspective of the operations research community; and Chapter 6 of Ref. 6, which can be downloaded from <http://web.mit.edu/dimitrib/www/dpchapter.html>.

A GENERIC ADP ALGORITHM

Equation (2) (or Eq. 3) is typically solved by stepping backward in time, where it is necessary to loop over all the potential states to compute $V_t(S_t)$ for each state S_t . For this reason, classical dynamic programming is often referred to as *backward dynamic programming*. The requirement of looping over all the states is the first computational step that cannot be performed when the state variable is a vector, or even a scalar continuous variable.

ADP takes a very different approach. In most ADP algorithms, we step forward in time following a single sample path. Assume we are modeling a finite horizon problem. We are going to iteratively simulate this problem.

At iteration n , assume that at time t we are in state S_t^n . Now assume that we have a policy of some sort that produces a decision x_t^n . In ADP, we are typically solving a problem that can be written as

$$\begin{aligned} \hat{v}_t^n &= \max_{x_t} (C(S_t^n, x_t) \\ &\quad + \gamma \mathbb{E}[\bar{V}_{t+1}^{n-1}(S^M(S_t^n, x_t, W_{t+1})) | S_t]). \end{aligned} \quad (4)$$

Here, $\bar{V}_{t+1}^{n-1}(S_{t+1})$ is an approximation of the value of being in state $S_{t+1} = S^M(S_t^n, x_t, W_{t+1})$ at time $t+1$. If we are modeling a problem in steady state, we drop the subscript t everywhere, recognizing that W is a random variable. We note that x_t here can be a vector, where the maximization problem might require the use of a linear, nonlinear, or integer programming package. Let x_t^n be the value of x_t that solves this optimization problem. We can use $\hat{v}_t^n$ to update our approximation of the value function. For example, if we are using a lookup table representation, we might use

$$\bar{V}_t^n(S_t^n) = (1 - \alpha_{n-1})\bar{V}_t^{n-1}(S_t^n) + \alpha_{n-1}\hat{v}_t^n, \quad (5)$$

where α_{n-1} is a step size between 0 and 1 (more on this later).

Now we are going to use Monte Carlo methods to sample our vector of random variables, which we denote by W_{t+1}^n , representing the new information that would have first been learned between time t and $t+1$. The next state would be given by

$$S_{t+1}^n = S^M(S_t^n, x_t^n, W_{t+1}^n).$$

The overall algorithm is given in Fig. 1. This is a very basic version of an ADP algorithm, one which would generally not work in practice. But it illustrates some of the basic elements of an ADP algorithm. First, it steps forward in time, using a randomly sampled set of outcomes, visiting one state at a time. Secondly, it makes decisions using some sort of statistical approximation of a value function, although it is unlikely that we would use a lookup table representation. Thirdly, we use information gathered as we step forward in time to update our value function approximation, almost always using some sort of recursive statistics.

Step 0. Initialization:

Step 0a. Initialize $\bar{V}_t^0(S_t)$ for all states S_t .

Step 0b. Choose an initial state S_0^1 .

Step 0c. Set $n = 1$.

Step 1. Choose a sample path ω^n .

Step 2. For $t = 0, 1, 2, \dots, T$ do:

Step 2a. Solve

$$\hat{v}_t^n = \max_{x_t \in \mathcal{X}_t^n} \left(C_t(S_t^n, x_t) + \gamma \mathbb{E} \bar{V}_{t+1}^{n-1}(S^M(S_t^n, x_t, W_{t+1}^n)) \right)$$

and let x_t^n be the value of x_t that solves the maximization problem.

Step 2b. Update $\bar{V}_t^{n-1}(S_t)$ using

$$\bar{V}_t^n(S_t) = \begin{cases} (1 - \alpha_{n-1})\bar{V}_t^{n-1}(S_t^n) + \alpha_{n-1}\hat{v}_t^n & S_t = S_t^n \\ \bar{V}_t^{n-1}(S_t) & \text{otherwise.} \end{cases}$$

Step 2c. Compute the next state to visit. This may be chosen at random (according to some distribution), or from

$$S_{t+1}^n = S^M(S_t^n, x_t^n, W_{t+1}^n).$$

Step 3. Let $n = n + 1$. If $n < N$, go to step 1.

Figure 1. An approximate dynamic programming algorithm using expectations.

The algorithm in Fig. 1 goes under different names. It is a basic “forward pass” algorithm, where we step forward in time, updating value functions as we progress. Another variation involves simulating forward through the horizon without updating the value function. Then, after the simulation is done, we step backward through time, using information about the entire future trajectory.

We have written the algorithm in the context of a finite horizon problem. For infinite horizon problems, simply drop the subscript t everywhere, remembering that you have to keep track of the “current” and “future” state.

There are different ways of presenting this basic algorithm. To illustrate, we can rewrite Equation (5) as

$$\bar{V}^n(S_t^n) = \bar{V}^{n-1}(S_t^n) + \alpha_{n-1}(\hat{v}_t^n - \bar{V}^{n-1}(S_t^n)). \quad (6)$$

The quantity

$$\begin{aligned} \hat{v}_t^n - \bar{V}^{n-1}(S_t^n) &= C_t(S_t^n, x_t) + \gamma \bar{V}_{t+1}^{n-1} \\ &\quad \times (S_{t+1}) - \bar{V}^{n-1}(S_t^n) \end{aligned}$$

where

$$S_{t+1} = S^M(S_t, x_t, W_{t+1})$$

is known as the *Bellman error*, since it is a sampled observation of the difference between what we think is the value of being in state S_t^n and an estimate of the value of being in state S_t^n . In the RL community, it has long been called the *temporal difference (TD)*, since it is the difference between estimates at two different iterations, which can have the interpretation of time, especially for steady-state problems, where n indexes transitions forward in time.

The RL community would refer to this algorithm as TD learning (first introduced in Ref. 7). If we use a backward pass, we can let $\hat{v}_t^n$ be the value of the entire future trajectory, but it is often useful to introduce a discount factor (usually represented as λ) to discount rewards received in the future. This discount factor is introduced purely for algorithmic reasons, and should not be confused with the discount γ , which is intended

to capture the time value of money. If we let $\lambda = 1$, then we are adding up the entire future trajectory. But if we use $\lambda = 0$, then we obtain the same updating as our forward pass algorithm in Fig. 1. For this reason, the RL community refers to this family of updating strategies as $TD(\lambda)$.

$TD(0)$ (TD learning with $\lambda = 0$) can be viewed as an approximate version of classical value iteration. It is important to recognize that after each update, we are not just changing the value function approximation, we are also changing our behavior (i.e., our policy for making decisions), which in turn changes the distribution of $\hat{v}_t^n$ given a particular state S_t^n . $TD(1)$, on the other hand, computes $\hat{v}_t^n$ by simulating a policy into the future. This policy depends on the value function approximation, but otherwise $\hat{v}_t^n$ does not directly use value function approximations.

An important dimension of most ADP algorithms is Step 2c, where we have to choose which state to visit next. For many complex problems, it is most natural to choose the state determined by the action x_t^n , and then simulate our way to the next state using $S_{t+1}^n = S^M(S_t^n, x_t^n, W_{t+1}(\omega^n))$. Many authors refer to this as a form of “real-time dynamic programming” (RTDP) [8], although a better term is trajectory following [9], since RTDP involves other algorithmic assumptions. The alternative to trajectory following is to randomly generate a state to visit next. Trajectory following often seems more natural since it means you are simulating a system, and it visits the states that arise naturally, rather than from what might be an unrealistic probability model. But readers need to understand that there are few convergence results for trajectory following models, due to the complex interaction between random observations of the value of being in a state and the policy that results from a specific value function approximation, which impacts the probability of visiting a state.

The power and flexibility of ADP has to be tempered with the reality that simple algorithms generally do not work, even on simple problems. There are several issues we have to address if we want to develop an effective ADP strategy:

- We avoid the problem of looping over all the states, but replace it with the problem of developing a good statistical approximation of the value of being in each state that we might visit. The challenge of designing a good value function approximation is at the heart of most ADP algorithms.
- We have to determine how to update our approximation using new information.
- We assume that we can compute the expectation, which is often not the case, and which especially causes problems when our decision/action variable is a vector.
- We can easily get caught in a circle of choosing actions that take us to states that we have already visited, simply because we may have pessimistic estimates of states that we have not yet visited. We need some mechanism to force us to visit states just to learn the value of these states.

The remainder of this article is a brief tour through a rich set of algorithmic strategies for solving these problems.

Q-LEARNING AND THE POSTDECISION STATE VARIABLE

In our classical ADP strategy, we are solving optimization problems of the form

$$\begin{aligned} \hat{v}_t^n = \max_{x_t \in \mathcal{X}_t^n} & (C(S_t^n, x_t) \\ & + \gamma \mathbb{E}[\bar{V}_{t+1}(S^M(S_t^n, x_t, W_{t+1})) | S_t]). \end{aligned} \quad (7)$$

There are many applications of ADP, which introduce additional complications: (i) we may not be able to compute the expectation, and (ii) the decision x may be a vector, and possibly a very big vector (thousands of dimensions). There are two related strategies that have evolved to address these issues: *Q*-learning, a technique widely used in the RL community, and ADP using the post-decision state variable, a method that has evolved primarily in the operations research community. These methods are actually closely related, a topic we revisit at the end.

Q-Factors

To introduce the idea of *Q*-factors, we need to return to the notation where a is a discrete action (with a small action space). The *Q* factor (so named because this was the original notation used in Ref. 10) is the value of being in a state *and* taking a specific action,

$$Q(s, a) = C(s, a) + \gamma \mathbb{E} \bar{V}(S^M(S^n, a, W)).$$

Value functions and *Q*-factors are related using

$$V(s) = \max_a Q(s, a),$$

so, at first glance it might seem as if we are not actually gaining anything. In fact, estimating a *Q*-factor actually seems harder than estimating the value of being in a state, since there are more state-action pairs than there are states.

The power of *Q*-factors arises when we have problems where we either do not have an explicit transition function $S^M(\cdot)$, or do not know the probability distribution of W . This means we cannot compute the expectation, but not because it is computationally difficult. When we do not know the transition function, and/or cannot compute the expectation (because we do not know the probability distribution of the random variable), we would like to draw on a subfield of ADP known as *model-free* dynamic programming. In this setting, we are in state S^n , we choose an action a^n , and then observe the next state, which we will call s' . We can then record a value of being in state s and taking action a using

$$\hat{q}^n = C(S^n, a^n) + \bar{V}^{n-1}(s')$$

where $\bar{V}(s') = \max_{a'} Q^{n-1}(s', a')$. We then use this value to update our estimate of the *Q*-factor using

$$Q^n(S^n, a^n) = (1 - \alpha) Q^{n-1}(S^n, a^n) + \alpha \hat{q}^n.$$

Whenever we are in state S^n , we choose our action using

$$a^n = \arg \max_a Q^{n-1}(S^n, a). \quad (8)$$

Note that we now have a method that does not require a transition function or the need to compute an expectation, we only need access to some exogenous process that tells us what state we transition to, given a starting state and an action.

The Postdecision State Variable

A closely related strategy is to break the transition function into two steps: the pure effect of the decision x_t , and the effect of the new, random information W_{t+1} . In this section, we use the notation of operations research, because what we are going to do is enable the solution of problems where x_t may be a very large vector. We also return to time-dependent notation since it clarifies when we are measuring a particular variable.

We can illustrate this idea using a simple inventory example. Let S_t be the amount of inventory on hand at time t . Let x_t be an order for a new product, which we assume arrives immediately. The typical inventory equation would be written as

$$S_{t+1} = \max\{0, S_t + x_t - \hat{D}_{t+1}\}$$

where $\hat{D}_{t+1}$ is the random demand that arises between t and $t + 1$. We denote the pure effect of this order using

$$S_t^x = S_t + x_t.$$

The state S_t^x is referred to as the *postdecision state* [11], which is the state at time t , immediately after a decision has been made, but before any new information has arrived. The transition from S_t^x to S_{t+1} in this example would then be given by

$$S_{t+1} = \max\{0, S_t^x - \hat{D}_{t+1}\}.$$

Another example of a postdecision state is a tic-tac-toe board after you have made your move, but before your opponent has moved. Reference 5 refers to this as the after-state variable, but we prefer the notation that emphasizes the information content (which is why S_t^x is indexed by t).

A different way of representing a postdecision state is to assume that we have a forecast $\bar{W}_{t,t+1} = \mathbb{E}\{W_{t+1}|S_t\}$, which is a point

estimate of what we think W_{t+1} will be given what we know at time t . A postdecision state can be thought of as a forecast of the state S_{t+1} given what we know at time t , which is to say

$$S_t^x = S^M(S_t, x_t, \bar{W}_{t,t+1}).$$

This approach will seem more natural in certain applications, but it would not be useful when random variables are discrete. Thus, it makes sense to use the expected demand, but not the expected action of your tic-tac-toe opponent.

In a typical decision tree, S_t would represent the information available at a decision node, while S_t^x would be the information available at an outcome node. Using these two steps, Bellman's equations become

$$V_t(S_t) = \max_{x_t} (C(S_t, x_t) + \gamma V_t^x(S_t^x)), \quad (9)$$

$$V_t^x(S_t^x) = \mathbb{E}\{V_{t+1}(S_{t+1})|S_t\}. \quad (10)$$

Note that Equation (9) is now a deterministic optimization problem, while Equation (10) involves only an expectation. Of course, we still do not know $V_t^x(S_t^x)$, but we can approximate it just as we would approximate $V_t(S_t)$. However, now we have to pay attention to the nature of the optimization problem. If we are just searching over a small number of discrete actions, we do not really have to worry about the structure of our approximate value function around S_t^x . But if x is a vector, which might have hundreds or thousands of discrete or continuous variables, then we have to recognize that we are going to need some sort of solver to handle the maximization problem.

To illustrate the basic idea, assume that we have discrete states and are using a lookup table representation for a value function. We would solve Equation (9) to obtain a decision x_t^n , and we would then simulate our way to S_{t+1}^n using our transition function. Let $\hat{v}_t^n$ be the objective function returned by solving Equation (9) at time t , when we are in state S_t^n . We would then use this value to update the value at the *previous postdecision state*. That is,

$$\bar{V}_{t-1}^n(S_{t-1}^n) = (1 - \alpha_{n-1})\bar{V}_{t-1}^{n-1}(S_{t-1}^n) + \alpha_{n-1}\hat{v}_t^n. \quad (11)$$

Thus, the updating is virtually the same as we did before; it is just that we are now using our estimate of the value of being in a state to update the value of the previous postdecision state. This is a small change, but it has a huge impact by eliminating the expectation in the decision problem.

Now imagine that we are managing different types of products, where S_{ti} is the inventory of product of type i , and S_{ti}^x is the inventory after placing a new order. We might propose a value function approximation that looks like

$$\bar{V}_t^x(S_t^x) = \sum_i \left(\theta_{1i} S_{ti}^x - \theta_{2i} (S_{ti}^x)^2 \right).$$

This value function is separable and concave in the inventory (assuming $\theta_{2i} > 0$). Using this approximation, we can probably solve our maximization problem using a nonlinear programming algorithm, which means we can handle problems with hundreds or thousands of products. Critical to this step is that the objective function in Equation (9) is deterministic.

Comments

On first glance, Q -factors and ADP using the postdecision state variable seem to be very different methods to address very different problems. However, there is a mathematical commonality to these two algorithmic strategies. First, we note that if S is our current state, (S, a) is a kind of postdecision state, in that it is a deterministic function of the state and action. Second, if we take a close look at Equation (9), we can write

$$Q(S_t, x_t) = C(S_t, x_t) + \gamma V_t^x(S_t^x).$$

We assume that we have a known function S_t^x that depends only on S_t and x_t , but we do not require the full transition function (which takes us to time $t + 1$), and we do not have to take an expectation. However, rather than develop an approximation of the value of a state and an action, we only require the value of a (postdecision) state. The task of finding the best action from a set of Q -factors (Eq. 8) is identical to the maximization problem in Equation (9). What has been overlooked in the ADP/RL community is that this

step makes it possible to search over large, multidimensional (and potentially continuous) action spaces. Multidimensional action spaces are a relatively overlooked problem class in the ADP/RL communities.

APPROXIMATE POLICY ITERATION

An important variant of ADP is approximate policy iteration, which is illustrated in Fig. 2 using the postdecision state variables. In this strategy, we simulate a policy, say, M times over the planning horizon (or M steps into the future). During these inner iterations, we fix the policy (i.e., we fix the value function approximation used to make a decision) to obtain a better estimate of the value of being in a state. The general process of updating the value function approximation is handled using the update function $U^V(\cdot)$. As $M \rightarrow \infty$, we obtain an exact estimate of the value of being in a particular state, while following a fixed policy (see Ref. 12 for the convergence theory of this technique).

If we randomize on the starting state and repeat this simulation for an infinite number of times, we can obtain the best possible value function given a particular approximation. It is possible to prove convergence of classical stochastic approximation methods when the policy is fixed. Unfortunately, there are very few convergence results when we combine sampled observations of the value of being in a state with changes in the policy.

If we are using low-dimensional representations of the value function (as occurs with basis functions), it is important that our update be of sufficient accuracy. If we use $M = 1$, which means we are updating after a single forward traversal, the result may mean that the value function approximation (and therefore the policy) is changing too rapidly from one iteration to another. The resulting algorithm may actually diverge [13,14].

TYPES OF VALUE FUNCTION APPROXIMATIONS

At the heart of approximate dynamic programming is approximating the value of

Figure 2. Approximate policy iteration using value function-based policies.

being in a state. It is important to emphasize that the problem of designing and estimating a value function approximation draws on the entire field of statistics and machine learning. Below, we discuss two very general approximation methods. You will generally find that ADP is opening a doorway into the field of machine learning, and that this is the place where you will spend most of your time. You should pick up a good reference book such as Ref. 15 on statistical learning methods, and keep an open mind regarding the best method for approximating a value function (or the policy directly).

Lookup Tables with Aggregation

The simplest form of statistical learning uses the lookup table representation that we first illustrated in Equation (5). The problem with this method is that it does not apply to continuous states, and requires an exponentially large number of parameters (one per state) when we encounter vector-valued states.

A popular way to overcome large state spaces is through aggregation. Let $\mathcal{S}$ be the

set of states. We can represent aggregation using

$$G^g : \mathcal{S} \rightarrow \mathcal{S}^{(g)}.$$

$\mathcal{S}^{(g)}$ represents the g^{th} level of aggregation of the state space $\mathcal{S}$, where we assume that $\mathcal{S}^{(0)} = \mathcal{S}$. Let

- $s^{(g)} = G^g(s)$, the g^{th} level aggregation of state s .
- $\mathcal{G}$ = The set of indices corresponding to the levels of aggregation.

We then define $\bar{V}^g(s)$ to be the value function approximation for state $s \in \mathcal{S}^{(g)}$.

We assume that the family of aggregation functions $G^g, g \in \mathcal{G}$ is given. A common strategy is to pick a single level of aggregation that seems to work well, but this introduces several complications. First, the best level of aggregation changes as we acquire more data, creating the challenge of working out how to transition from approximating the value function in the early iterations versus later iterations. Second, the right level of

aggregation depends on how often we visit a region of the state space.

A more natural way is to use a weighted average. At iteration n , we can approximate the value of being in state s using

$$\bar{v}^n(s) = \sum_{g \in \mathcal{G}} w^{(g,n)}(s) \bar{v}^{(g,n)}(s).$$

where $w^{(g,n)}(s)$ is the weight given to the g^{th} level of aggregation when measuring state s . This weight is set to zero, if there are no observations of states $s \in \mathcal{S}^{(g)}$. Thus, while there may be an extremely large number of states, the number of positive weights at the most disaggregate level $w^{(0,n)}$ is never greater than the number of observations. Typically, the number of positive weights at more aggregate levels will be substantially smaller than this.

There are different ways to determine these weights, but an effective method is to use weights that are inversely proportional to the total squared variation of each estimator. Let

$\bar{\sigma}^2(s)^{(g,n)}$	the variance of the estimate of the value of state s at the g^{th} level of aggregation after collecting n observations,
$\bar{\mu}^{(g,n)}(s)$	an estimate of the bias due to aggregation.

We can then use weights that satisfy

$$w^{(g)}(s) \propto \left((\bar{\sigma}^2(s))^{(g,n)} + (\bar{\mu}^{(g,n)}(s))^2 \right)^{-1}. \quad (14)$$

The weights are then normalized so that they sum to one. The quantities $\bar{\sigma}^2(s)^{(g,n)}$ and $\bar{\mu}^{(g,n)}(s)$ are computed using the following:

$$\begin{aligned} (\bar{\sigma}^2(s))^{(g,n)} &= \text{Var}[\bar{v}^{(g,n)}(s)] \\ &= \lambda^{(g,n)}(s) (s^2(s))^{(g,n)}, \end{aligned} \quad (15)$$

$$(s^2(s))^{(g,n)} = \frac{\bar{v}^{(g,n)}(s) - (\bar{\beta}^{(g,n)}(s))^2}{1 + \lambda^{n-1}}, \quad (16)$$

$$\lambda^{(g,n)}(s) = \begin{cases} (\alpha^{(g,n-1)}(s))^2, & n = 1, \\ (1 - \alpha^{(g,n-1)}(s))^2 \\ \quad \times \lambda^{(g,n-1)}(s) \\ \quad + (\alpha^{(g,n-1)}(s))^2, & n > 1, \end{cases} \quad (17)$$

$$\begin{aligned} \bar{v}^{(g,n)}(s) &= (1 - \alpha_{n-1}) \bar{v}^{(g,n-1)}(s) \\ &\quad + \alpha_{n-1} (\bar{v}^{(g,n-1)}(s) - \hat{v}^n(s))^2, \end{aligned} \quad (18)$$

$$\begin{aligned} \bar{\beta}^{(g,n)}(s) &= (1 - \alpha_{n-1}) \bar{\beta}^{(g,n-1)}(s) \\ &\quad + \alpha_{n-1} (\hat{v}^n - \bar{v}^{(g,n-1)}(s)), \end{aligned} \quad (19)$$

$$\bar{\mu}^{(g,n)}(s) = \bar{v}^{(g,n)}(s) - \bar{v}^{(0,n)}(s). \quad (20)$$

The term $\bar{v}^{(g,n)}(s)$ is the total squared variation in the estimate, which includes variation due to pure noise, $(s^2(s))^{(g,n)}$, and two sources of bias. The term $\bar{\beta}^{(g,n)}(s)$ is the bias introduced when smoothing a nonstationary data series (if the series is steadily rising, our estimates are biased downward), and $\bar{\mu}^{(g,n)}(s)$ is the bias due to aggregation error.

This system for computing weights scales easily to large state spaces. As we collect more observations of states in a particular region, the weights gravitate toward putting more weight on disaggregate estimates, while keeping higher weights on more aggregate estimates for regions that are only lightly sampled. For more on this strategy, see Ref. 16 or Chapter 7 in Ref. 2. For other important references on aggregation see Refs 4, 17, 18 and 19.

Basis Functions

Perhaps the most widely cited method for approximating value functions uses the concept of basis functions. Let

$\mathcal{F}$	A set of features drawn from a state vector,
$\phi_f(S)$	A scalar function that draws what is felt to be a useful piece of information from the state variable, for $f \in \mathcal{F}$.

The function $\phi_f(S)$ is referred to as a *basis function*, since in an ideal setting we would have a family of functions that spans the state space, allowing us to write

$$V(S|\theta) = \sum_{f \in \mathcal{F}} \theta_f \phi_f(S).$$

for an appropriately chosen vector of parameters θ . In practice, we cannot guarantee that we can find such a set of basis functions, so we write

$$\bar{V}(S|\theta) \approx \sum_{f \in \mathcal{F}} \theta_f \phi_f(S).$$

Basis functions are typically referred to as *independent variables* or *covariates* in the statistics community. If S is a scalar variable, we might write

$$\bar{V}(S|\theta) = \theta_0 + \theta_1 S + \theta_2 S^2 + \theta_3 \sin(S) + \theta_4 \ln(S).$$

This type of approximation is referred to as *linear*, since it is linear in the parameters. However, it is clear that we are capturing nonlinear relationships between the value function and the state variable.

There are several ways to estimate the parameter vector. The easiest, which is often referred to as *least squares temporal differencing* (LSTD), uses $\hat{v}_t^n$ as it is calculated in Equation (4), which means that it depends on the value function approximation. An alternative is least squares policy estimation (LSPE), where we use repeated samples of rewards from simulating a fixed policy. The basic LSPE algorithm estimates the parameter vector θ by solving

$$\theta^n = \arg \max_{\theta} \sum_{m=1}^n \left(\hat{v}_t^m - \sum_{f \in \mathcal{F}} \theta_f \phi_f(S_t^m) \right)^2.$$

This algorithm provides nice convergence guarantees, but the updating step becomes more and more expensive as the algorithm progresses. Also, it is putting equal weight on all iterations, a property that is not desirable in practice. We refer the reader to Ref. 6 for a more thorough discussion of LSTD and LSPE.

A simple alternative uses a stochastic gradient algorithm. Assuming we have an initial estimate θ^0 , we can update the estimate of theta at iteration n using

$$\begin{aligned} \theta^n &= \theta^{n-1} - \alpha_{n-1} (\bar{V}_t(S_t^n | \theta^{n-1}) - \hat{v}_t^n) \nabla_{\theta} \bar{V}_t \\ &\quad \times (S_t^n | \theta^{n-1}) \end{aligned}$$

$$\begin{aligned} &= \theta^{n-1} - \alpha_{n-1} (\bar{V}(S_t^n | \theta^{n-1}) - \hat{v}^n(S_t^n)) \\ &\quad \times \begin{pmatrix} \phi_1(S_t^n) \\ \phi_2(S_t^n) \\ \vdots \\ \phi_F(S_t^n) \end{pmatrix}. \end{aligned} \quad (21)$$

Here, α_{n-1} is a step size, but it has to perform a scaling function, so it is not necessarily less than 1. Depending on the problem, we might have a step size that starts around 10^6 or 0.00001.

A more powerful strategy uses recursive least squares. Let ϕ^n be the vector created by computing $\phi(S^n)$ for each feature $f \in \mathcal{F}$. The parameter vector θ can be updated using

$$\theta^n = \theta^{n-1} - H^n \phi^n \hat{\varepsilon}^n, \quad (22)$$

where ϕ^n is the vector of basis functions evaluated at S^n , and $\hat{\varepsilon}^n = \bar{V}(S_t^n | \theta^{n-1}) - \hat{v}^n(S_t^n)$ is the error in our prediction of the value function. The matrix H^n is computed using

$$H^n = \frac{1}{\gamma^n} B^{n-1}. \quad (23)$$

B^{n-1} is an $F+1$ by $F+1$ matrix (where $F = |\mathcal{F}|$), which is updated recursively using

$$B^n = B^{n-1} - \frac{1}{\gamma^n} (B^{n-1} \phi^n (\phi^n)^T B^{n-1}). \quad (24)$$

γ^n is a scalar computed using

$$\gamma^n = 1 + (\phi^n)^T B^{n-1} \phi^n. \quad (25)$$

Note that there is no step size in these equations. These equations avoid the scaling issues of the stochastic gradient update in Equation (21), but hide the fact that they are implicitly using a step size of $1/n$. This can be very effective, but can work very poorly. We can overcome this by introducing a factor λ and revising the updating of γ^n and B^n using

$$\gamma^n = \lambda + (x^n)^T B^{n-1} x^n, \quad (26)$$

and the updating formula for B^n , which is now given by

$$B^n = \frac{1}{\lambda} \left(B^{n-1} - \frac{1}{\gamma^n} (B^{n-1} x^n (x^n)^T B^{n-1}) \right).$$

This method puts a weight of λ^{n-m} on an observation from iteration $n - m$. If $\lambda = 1$, then we are weighting all observations equally. Smaller values of λ put a lower weight on earlier observations. See Chapter 7 of Ref. 2 for a more thorough discussion of this strategy. For a thorough presentation of recursive estimation methods for basis functions in ADP, we encourage readers to see Ref. 19.

Values versus Marginal Values

There are many problems, where it is more effective to use the derivative of the value function with respect to a state, rather than the value of being in the state. This is particularly powerful in the context of resource allocation problems, where we are solving a vector-valued decision problem using linear, nonlinear, or integer programming. In these problem classes, the derivative of the value function is much more important than the value function itself. This idea has long been recognized in the control theory community, which has used the term *heuristic dynamic programming* to refer to ADP using the value of being in a state, and “*dual heuristic*” dynamic programming when using the derivative (see Ref. 20 for a nice discussion of these topics from a control-theoretic perspective). Chapters 11 and 12 in Ref. 2 discuss the use of derivatives for applications that arise in operations research.

Discussion

Approximating value functions can be viewed as just an application of a vast array of statistical methods to estimate the value of being in a state. Perhaps the biggest challenge is model specification, which can include designing the basis functions. See Refs 14 and 21 for a thorough discussion of feature selection. There has also been considerable interest in the use of nonparametric methods [22]. An excellent reference for statistical learning techniques that can be used in this setting is Ref. 15.

The estimation of value function approximations, however, involves much more than just a simple application of statistical methods. There are several issues that have to be addressed that are unique to the ADP setting:

1. Value function approximations have to be estimated recursively. There are many statistical methods that depend on estimating a model from a fixed batch of observations. In ADP, we have to update value function approximations after each observation.
2. We have to get through the early iterations. In the first iteration, we have no observations. After 10 iterations, we have to work with value functions that have been approximated using 10 data points (even though we may have hundreds or thousands of parameters to estimate). We depend on the value function approximations in these early iterations to guide decisions. Poor decisions in the early iterations can lead to poor value function approximations.
3. The value $\hat{v}_t^n$ depends on the value function approximation $\bar{V}_{t+1}(S)$. Errors in this approximation produce biases in $\hat{v}_t^n$, which then distorts our ability to estimate $\bar{V}_t(S)$. As a result, we are recursively estimating value functions using nonstationary data.
4. We can choose which state to visit next. We do not have to use $S_{t+1}^n = S^M(S_t^n, x_t^n, W_{t+1}^n)$, which is a strategy known as *trajectory following*. This is known in the ADP community as the “*exploration vs. exploitation*” Problem—do we explore a state just to learn about it, or do we visit a state that appears to be the best? Although considerable attention has been given to this problem, it is a largely unresolved issue, especially for high-dimensional problems.
5. Everyone wants to avoid the art of specifying value function approximations. Here, the ADP community shares the broader goal of the statistical learning community, which is a method that will approximate a value function with no human intervention.

THE LINEAR PROGRAMMING METHOD

The best-known methods for solving dynamic programs (in steady state) are value iteration and policy iteration. Less well known is that we can solve for the value of being in each (discrete) state by solving the linear program

$$\min_v \sum_{s \in S} \beta_s v(s) \quad (27)$$

subject to

$$\begin{aligned} v(s) &\geq C(s, a) \\ &+ \gamma \sum_{s' \in S} p(s'|s, a) v(s') \text{ for all } s \text{ and } a, \end{aligned} \quad (28)$$

where β is simply a vector of positive coefficients. In this problem, the decision variable is the value $v(s)$ of being in state s , which has to satisfy the constraints (Eq. 26). The problem with this method is that there is a decision variable for each state, and a constraint for each state-action pair. Not surprisingly, this can produce very large linear programs very quickly.

The linear programming method received a new lease on life with the work of de Farias and Van Roy [23], who introduced ADP concepts to this method. The first step to reduce complexity involves introducing basis functions to simplify the representation of the value function, giving us

$$\min_{\theta} \sum_{s \in S} \beta_s \sum_{f \in \mathcal{F}} \theta_f \phi_f(s)$$

subject to

$$\begin{aligned} \sum_{f \in \mathcal{F}} \theta_f \phi_f(s) &\geq C(s, a) + \gamma \sum_{s' \in S} p(s'|s, a) \\ &\sum_{f \in \mathcal{F}} \theta_f \phi_f(s') \text{ for all } s \text{ and } a. \end{aligned}$$

Now, we have reduced a problem with $|S|$ variables (one value per state) to a vector $\theta_f, f \in \mathcal{F}$. Much easier, but we still have the problem of too many constraints. de Farias and Van Roy [23] then introduced the novel idea of using a Monte Carlo sample of the constraints. As of this writing, this method

is receiving considerable attention in the research community, but as with all ADP algorithms, considerable work is needed to produce robust algorithms that work in an industrial setting.

STEP SIZES

While designing a good value function, approximations are the most central challenge in the design of an ADP algorithm; a critical and often overlooked choice is the design of a step size rule. This is not to say that step sizes have been ignored in the research literature, but it is frequently the case that developers do not realize the dangers arising from an incorrect choice of step size rule.

We can illustrate the basic challenge in the design of a step size rule by considering a very simple dynamic program. In fact, our dynamic program has only one state and no actions. We can write it as computing the following expectation

$$F = \mathbb{E} \sum_{t=0}^{\infty} \gamma^t \hat{C}_t.$$

Assume that the contributions $\hat{C}_t$ are identically distributed as a random variable $\hat{C}$ and that $\mathbb{E}\hat{C} = c$. We know that the answer to this problem is $c/(1 - \gamma)$, but assume that we do not know c , and we have to depend on random observations of $\hat{C}$. We can solve this problem using the following two-step algorithm:

$$\hat{v}^n = \hat{C}^n + \gamma \bar{v}^{n-1}, \quad (29)$$

$$\bar{v}^n = (1 - \alpha_{n-1}) \bar{v}^{n-1} + \alpha_{n-1} \hat{v}^n. \quad (30)$$

We are using an iterative algorithm, where $\bar{v}^n$ is our estimate of F after n iterations. We assume that $\hat{C}^n$ is the n^{th} sample realization of $\hat{C}$.

We note that Equation (29) handles the problem of summing over multiple contributions. Since we depend on Monte Carlo observations of $\hat{C}$, we use Equation (30) to then perform smoothing. If $\hat{C}$ were deterministic, we would use a step size $\alpha_{n-1} = 1$ to achieve the fastest convergence. On the other hand,

if $\hat{C}$ is random, but if $\gamma = 0$ (which means we do not really have to deal with the infinite sum), then the best possible step size is $1/n$ (we are just trying to estimate the mean of $\hat{C}$). In fact, $1/n$ satisfies a common set of theoretical conditions for convergence which are typically written

$$\sum_{n=1}^{\infty} \alpha_n = \infty, \\ \sum_{n=1}^{\infty} (\alpha_n)^2 < \infty.$$

The first of these conditions prevents stalling (a step size of 0.8^n would fail this condition), while the second ensures that the variance of the resulting estimate goes to zero (statistical convergence).

Not surprisingly, many step size formulas have been proposed in the literature. A review is provided in Ref. 24 (see also Chapter 6 in Ref. 2). Two popular step size rules that satisfy the conditions above are

$$\alpha_n = \frac{a}{a + n - 1}, \quad \text{and} \\ \alpha_n = \frac{1}{n^\beta}.$$

In the first formula, $a = 1$ gives you $1/n$, whereas larger values of a produce a step size that declines more slowly. In the second rule, β has to satisfy $0.5 < \beta \leq 1$. Of course, these rules can be combined, but both a and β have to be tuned, which can be particularly annoying.

Reference 24 introduces the following step size rule (called the *bias adjusted Kalman filter* (BAKF) step size rule):

$$\alpha_n = 1 - \frac{\sigma^2}{(1 + \lambda^n)\sigma^2 + (\beta^n)}, \quad (31)$$

where

$$\lambda^n = \begin{cases} (\alpha_{n-1})^2, & n = 1 \\ (1 - \alpha_{n-1})^2 \lambda^{n-1} + (\alpha_{n-1})^2, & n > 1. \end{cases}$$

Here, σ^2 is the variance of the observation noise, and β^n is the bias measuring the difference between the current estimate of the

value function $\bar{V}^n(S^n)$ and the true value function $V(S^n)$. Since these quantities are not generally known they have to be estimated from data (see Refs 2 and 24, Chapter 6 for details).

This step size enjoys some useful properties. If there is no noise, then $\alpha_{n-1} = 1$. If $\beta^n = 0$, then $\alpha_{n-1} = 1/n$. It can also be shown that $\alpha_{n-1} \geq 1/n$ at all times. The primary difficulty is that the bias term has to be estimated from noisy data, which can cause problems. If the level of observation noise is very high, we recommend a deterministic step size formula. But if the observation noise is not too high, the BAKF rule can work quite well, because it adapts to the data.

PRACTICAL ISSUES

ADP is a flexible modeling and algorithmic framework that requires that a developer make a number of choices in the design of an effective algorithm. Once you have developed a model, designed a value function approximation, and chosen a learning strategy, you still face additional steps before you can conclude that you have an effective strategy.

Usually the first challenge you will face is debugging a model that does not seem to be working. For example, as the algorithm learns, the solution will tend to get better, although it is hardly guaranteed to improve from one iteration to the next. But what if the algorithm does not seem to produce any improvement at all?

Start by making sure that you are solving the decision problem correctly, given the value function approximation (even if it may be incorrect). This is really only an issue for more complex problems, such as where x is an integer-valued vector, requiring the use of more advanced algorithmic tools.

Then, most importantly, verify the accuracy of the information (such as $\hat{v}$) that you are deriving to update the value function. Are you using an estimate of the value of being in a state, or perhaps the marginal value of an additional resource? Is this value correct? If you are using a forward pass algorithm (where $\hat{v}$ depends on a value function approximation of the future), assume the

approximation is correct and validate $\hat{v}$. This is more difficult if you are using a backward pass (as with TD(1)), since $\hat{v}$ has to track the value (or marginal value) of an entire trajectory.

When you have confidence that $\hat{v}$ is correct, are you updating the value function approximation correctly? For example, if you compare $\hat{v}_t^n$ with $\bar{V}^{n-1}(S_t^n)$, the observations of $\hat{v}^n$ (over iterations) should look like the scattered noise of observations around an estimated mean. Do you see a persistent bias?

Finally, think about whether your value function approximations are really contributing better decisions. What if you set the value function to zero? What intelligence do you feel your value function approximations are really adding? Keep in mind that there are some problems where a myopic policy can work reasonably well.

Now, assume that you are convinced that your value function approximations are improving your solution. One of the most difficult challenges is evaluating the quality of an ADP solution. Perhaps you feel you are getting a good solution, but how far from optimal are you?

There is no single answer to the question of how to evaluate an ADP algorithm. Typically, you want to ask the question: If I simplify my problem in some way (without making it trivial), do I obtain an interesting problem that I can solve optimally? If so, you should be able to apply your ADP algorithm to this simplified problem, producing a benchmark against which you can compare.

How a problem might be simplified is situation specific. One strategy is to eliminate uncertainty. If the deterministic problem is still interesting (for example, this might be the case in a transportation application, but not a financial application), then this can be a powerful benchmark. Alternatively, it might be possible to reduce the problem to one that can be solved exactly as a discrete Markov decision process.

If these approaches do not produce anything, the only remaining alternative is to compare an ADP-based strategy against a policy that is being used (or most likely to be used) in practice. If it is not the best policy, is it at least an improvement? Of course, there

are many settings, where ADP is being used to develop a model to perform policy studies. In such situations, it is typically more important that the model behave reasonably. For example, do the results change in response to changes in inputs as expected?

ADP is more like a toolbox than a recipe. A successful model requires some creativity and perseverance. There are many instances of people who try ADP, only to conclude that it “does not work.” It is very easy to miss one ingredient to produce a model that does not work. But a successful model not only solves a problem, but it also enhances your ability to understand and solve complex decision problems.

APPROXIMATION ALGORITHMS FOR STOCHASTIC OPTIMIZATION PROBLEMS IN OPERATIONS MANAGEMENT

CONG SHI
University of Michigan,
Ann Arbor, MI, USA

INTRODUCTION

The difficulty of sifting through large amount of data in order to make an informed choice is ubiquitous nowadays, thanks to the advances in information technologies and high speed networking. One of the promises of the information technology era is that many decisions can now be made rapidly by computers, such as deciding inventory levels, routing vehicles, planning facility locations, managing revenue, and so on. Many of these applications can be modeled as discrete optimization problems. Unfortunately, most interesting discrete optimization problems and their stochastic variants are NP-hard. Thus, we cannot simultaneously have algorithms (i) that find optimal solution (ii) in polynomial time, and (iii) for any instance. In order to deal with such optimization problems, we need to relax at least one of the three requirements: relaxing the “for any instance” requirement, the requirement of polynomial-time solvability, or the requirement of finding an optimal solution. The third relaxation is the most common approach, where we only need to find a “good-enough” solution instead of the best one. Next, we formally define the notion of *approximation algorithms* for discrete optimization problems.

Definition 1 An α -approximation algorithm for an optimization problem is a polynomial-time algorithm that for all instances of the problem produces a solution whose value is within a factor of α of the value of an optimal solution.

For an α -approximation algorithm, we always call α the *performance guarantee*, *approximation ratio*, or *approximation factor* of the algorithm. We will follow the convention that $\alpha > 1$ for minimization problems, while $\alpha < 1$ for maximization problems.

For a particular class of problems of interest (e.g., knapsack problem and Euclidean traveling salesman problem), we are able to obtain extremely good approximation algorithms; in fact, these problems have *polynomial-time approximation schemes* (PTASs).

Definition 2 A PTAS is a family of algorithms $\{P(\epsilon)\}$, where there is an algorithm for each $\epsilon > 0$, such that $P(\epsilon)$ is a $(1 + \epsilon)$ -approximation algorithm for minimization problems or a $(1 - \epsilon)$ -approximation algorithm for maximization problems.

However, there exists a large class of interesting (but not so easy) problems called MAX SNP (e.g., max satisfiability problem and max cut problem), which fails to have a PTAS, unless $P = NP$.

There is a vast body of literature in both computer science and operations research devoted to designing approximation algorithms for deterministic discrete optimization problems. For an excellent and a detailed exposition on deterministic models, we refer interested readers to the following books: Ausiello *et al.* [1], Vazirani [2], and Williamson and Shmoys [3]. This article mainly focuses on approximation algorithms for stochastic optimization models arising in operations management, which have gained much momentum recently. Before giving an overview or a survey on the recent development, we would like to first provide readers some basic ideas of discrete optimization models *under uncertainty* through the following example.

A Stochastic Vertex Cover Problem

We first use a stochastic version of the vertex cover problem to motivate our discus-

sion of how approximation algorithms can be designed for stochastic optimization problems. We review the 2-approximation algorithm and its worst-case analysis by Ravi and Sinha [4].

A vertex cover of a graph is a set of vertices such that each edge of the graph is incident to at least one vertex of the set. Formally, a vertex cover of an undirected graph $G = (V, E)$ (vertices and edges) is a subset S of V such that, if an edge $(u, v) \in E$, then either $u \in S$ or $v \in S$ (or both). The set S is said to *cover* the edges of G . As picking each vertex $i \in V$ incurs a cost c_i , a *minimum vertex cover* is a vertex cover of smallest possible cost. A simple deterministic LP rounding algorithm yields a 2-approximation. The best-known approximation algorithm has performance ratio of $2 - \log \log |V| / (2 \log |V|)$, because of Monien and Speckenmeyer [5]. A lower bound of 1.16 on the hardness of approximating the problem was shown by Håstad [6]. We refer readers to the studies by Williamson and Shmoys [3] and Vazirani [2] for the extensive discussion of the deterministic vertex cover problem.

Now, we describe a two-stage stochastic version of the vertex cover problem. In the first stage, we are given a (undirected) graph $G = (V, E_0)$. In the stochastic version, the edges E that will be present in the second stage are uncertain *a priori*, and we only know its distributional information, that is, there are m possible scenarios, each consisting of a set of *realized* edges E_k with probability of occurrence p_k . Note that E_k ($k = 1, \dots, m$) may or may not be subsets of the first-stage edge set E_0 . The first-stage cost of vertex v is c_v^0 , and its cost in scenario k at the second-stage is c_v^k . The edges in $E_k \cap E_0$ may be covered in either the first or second stage, while edges in E_k/E_0 must be covered in the second stage. The objective is to identify a set of vertices to be selected in the first stage, so that the expected cost of extending this set to a vertex cover of the edges of the realized second-stage scenario is minimized.

Ravi and Sinha [4] provided a primal-dual algorithm that rounds the integer programming (IP) formulation of stochastic vertex cover. Variable x_v^k indicates whether or not vertex v is picked in scenario k (where $k = 0$

corresponds to the first stage). The IP formulation is given by

$$\begin{aligned} \min \quad & \sum_v c_v^0 x_v^0 + \sum_{k=1}^m p_k c_v^k x_v^k, \quad (\text{IP-SVC}) \\ \text{s.t.} \quad & x_u^0 + x_v^0 + x_u^k + x_v^k \geq 1, \quad \forall (u, v) \in E_k \cap E_0, \forall k, \\ & x_u^k + x_v^k \geq 1, \quad \forall (u, v) \in E_k/E_0, \forall k, \\ & x \in \mathbb{Z}_0^+. \end{aligned}$$

The LP relaxation of IP-SVC, called *LP-SVC*, replaces the constraint $x \in \mathbb{Z}_0^+$ by $x \geq 0$. Then, we write the dual of LP-SVC further. The dual variable y_e^k packs edge e in E_k if $e \in E_k$, and it packs e in E_0 if $e \in E_k \cap E_0$.

$$\begin{aligned} \max \quad & \sum_{k=1}^m \sum_{e \in E_0 \cup E_k} y_e^k, \quad (\text{DLP-SVC}) \\ \text{s.t.} \quad & \sum_{e \in E_k: v \in e} y_e^k \leq p_k c_v^k, \quad \forall v, \forall k, \\ & \sum_{k=1}^m \sum_{e \in E_0 \cap E_k: v \in e} y_e^k \leq c_v^0, \quad \forall v, \\ & y \geq 0. \end{aligned}$$

The algorithm π is a greedy dual-ascent type of primal-dual algorithm with two phases.

- (a) In the first phase, we raise the dual variable y_e^k uniformly for all edges in E_k/E_0 , separately for each k . All vertices that become tight (the first dual constraint packed to $p_k c_v^k$) have x_v^k set to 1 and deleted along with adjacent edges. We proceed this way until all edges in E_k/E_0 are covered and deleted.
- (b) In the second phase, we raise the dual variable y_e^k uniformly for all *uncovered* edges in E_k . Note that these uncovered edges are contained in $E_k \cap E_0$. If a vertex is tight for x_v^0 (i.e., second dual constraint packed to c_v^0), then we pick it in the first stage solution by setting $x_v^0 = 1$, and if it is not tight for x_v^0 (the first dual constraint packed to $p_k c_v^k$), then we pick it in the second stage by setting $x_v^k = 1$ as a recourse decision.

Theorem 1 (Ravi and Sinha [4]) *The integer program IP-SVC can be bounded by the primal-dual algorithm described earlier within a factor of 2 in polynomial time.*

Proof. Let the cost of DLP-SVC generated by π be C^π (DLP-SVC). In addition, let the optimal costs of LP-SVC and IP-SVC be C^* (LP-SVC) and C^* (IP-SVC), respectively. By linear programming (LP) duality,

$$C^\pi(\text{DLP-SVC}) \leq C^*(\text{LP-SVC}) \leq C^*(\text{IP-SVC}).$$

Now if π generates a feasible solution for IP-SVC and a cost C^π (IP-SVC), then it suffices to show that

$$\begin{aligned} C^\pi(\text{IP-SVC}) &\leq 2 \cdot C^\pi(\text{DLP-SVC}) \\ &= 2 \sum_{k=1}^m \sum_{e \in E_0 \cup E_k} y_e^k. \end{aligned}$$

The feasibility is rather obvious. Consider an edge $e = (u, v) \in E_k$ in scenario k . We must have picked one of its endpoints in either the first phase or the second phase (or both) by the construction of algorithm π .

To complete the proof, we shall show that, each time we set $x_v^k = 1$, we assign some dual variables to it such that (i) the sum of dual variables assigned to each such x_v^k variable has to equal $p_k c_v^k$ (where $p_0 = 1$) and (ii) each dual variable or each edge is assigned at most twice.

Consider a vertex v that was selected in scenario k in either the first or second phase. We assign all dual variables y_e^k such that v is incident to e . By construction of π , v is only chosen when the first constraint becomes tight, that is,

$$\sum_{e \in E_k: v \in e} y_e^k = p_k c_v^k, \quad \forall k, \quad (1)$$

thereby guaranteeing (i). An edge $e \in E_k/E_0$ is assigned to vertex v only if x_v^k is set to 1 for $k \neq 0$. Thus, (ii) for $e \in E_k/E_0$ is ensured because each edge has at most two vertices.

Then, we consider a vertex v for which x_v^0 is set to 1. By our construction of π , the second constraint has to be tight, that is,

$$\sum_{k=1}^m \sum_{e \in E_0 \cap E_k: v \in e} y_e^k = c_v^0,$$

and all edges in the sum are assigned to the variable x_v^0 , ensuring (i). In addition, as these edges in the sum are not assigned to any other variable x_v^k for $k \neq 0$ and each such edge has only two vertices, (ii) is maintained. $\square$

As shown in this example, instead of actually solving the dual LP (DLP-SVC), we can construct a feasible dual solution maintaining some desired properties. In this case, constructing the dual solution is much faster than solving the dual LP and, hence, leads to a much faster algorithm. Other common techniques for designing approximation algorithms include various rounding techniques, greedy algorithms, or randomized algorithms.

Literature Review

Traditionally, approximation algorithm techniques have been applied primarily to deterministic combinatorial optimization problems, for instance, the set cover problem, the knapsack problem, the bin-packing problem, the traveling salesman problem, scheduling problems, and so on. We refer interested readers to Ausiello *et al.* [1], Vazirani [2], and Williamson and Shmoys [3] for more details on various deterministic models. Our literature review will mainly focus on the design of approximation algorithms for stochastic optimization models, with emphasis on the recent development in various operations management models.

Stochastic optimization is a vast field, beginning with the works of Dantzig [7] and Beale [8] in the 1950s and seeing much activity until this day; we refer interested readers to the following books that survey the field: Birge and Louveaux [9], Kall and Wallace [10], Stougie and Van Der Vlerk [11], and Ruszczyński and Shapiro [12]. Stochastic optimization problems are often computationally quite difficult and often more difficult than their deterministic counterparts, both from the viewpoint of complexity theory and from a practical perspective. In many settings, the computational difficulty stems from the fact that the distribution might assign a

nonzero probability to an exponential number of scenarios, leading to a considerable increase in the problem complexity, a phenomenon often called the *curse of dimensionality*.

The work on approximation algorithms for stochastic combinatorial problems goes back to the work on stochastic scheduling problem of Möhring *et al.* [13, 14] and the more recent work of Möhring *et al.* [15]. By its very nature, scheduling algorithms often have to account for uncertainty in the sizes and arrival times of future jobs. Next, we will survey some recent development on approximation algorithms for these stochastic optimization models related to operations management. We attempt to divide the relevant work into three groups. The first group surveys the growing stream of approximation results for two-stage or multistage stochastic optimization models. These results are usually derived for general purposes and can be potentially applied to specific problems in operations management. The second group discusses the recent advances in designing approximation algorithms for stochastic inventory systems, with a summary of many key results. The third group presents relevant work in other core operations management models, such as scheduling, facility location, vehicle routing, and revenue management.

General Stochastic Optimization Models. The first worst-case analysis of approximation algorithms for two-stage stochastic programming problems was the work on service provisioning in a telecommunication network by Dye *et al.* [16]. Ravi and Sinha [4] studied two-stage stochastic versions of several combinatorial optimization problem (e.g., shortest path, vertex cover, facility location, set cover, and bin-packing problems) and provided nearly tight approximation algorithms for them when the number of scenarios is polynomial. Independently, Immorlica *et al.* [17] provided approximation algorithms for several covering and packing problems. Their model allowed for exponential scenarios (through an independent activation model) but the costs in the two stages have to be proportional.

Gupta *et al.* [18] were the first to consider the *black-box* model and provided sampling-based approximation algorithms for various two-stage problems with a proportional cost structure. In the black-box model, the underlying distribution is not specified exactly, but the algorithm has access to an oracle that can be used to sample from the underlying distribution, and the running time is measured in terms of the number of calls to this oracle. Gupta *et al.* [19] extended this boosted sampling framework for multistage stochastic optimization problems with recourse. Shmoys and Swamy [20–22] showed that one could derive a PTAS using sample average approximation and adapted ellipsoid methods for the exponentially large LP relaxations and, then, use a simple rounding approach to derive approximation algorithms for the original black-box model without any proportional cost assumption. Swamy and Shmoys [23] extended their results to multistage stochastic optimization problems and showed that the LP solution for each stage can be rounded to an integer solution independent of other stages. Charikar *et al.* [24] provided a general technique based on a sample average approximation that reduced the problem of obtaining a good approximation algorithm for the two-stage black-box model, to the problem of obtaining the analogous results in the polynomial scenario setting. Srinivasan [25] improved on the work of Swamy and Shmoys [23] by showing an approximability, which does not depend multiplicatively on the number of stages.

Dhamdhere *et al.* [26] introduced the robust version of two-stage combinatorial covering problems under uncertainty and provided approximation algorithms for them. There are also some recent works related to robust or risk-averse version under uncertainty (see Gupta *et al.* [27] on covering problems using a guess and prune idea, Golovin *et al.* [28] on two-stage min-cut and shortest path problems, and So *et al.* [29] on problems with controllable risk-aversion level).

Stochastic Inventory Systems. The concept of approximation algorithms has been

applied to several deterministic problems in inventory management, see Silver and Meal [30], Roundy [31], Levi *et al.* [32–34], Shen *et al.* [35], Cheung *et al.* [36]. We then focus on stochastic inventory systems.

The recent stream of research on designing approximation algorithms for the multiperiod stochastic inventory control problems was initiated by Levi *et al.* [37], who proposed a 2-approximation algorithm for the basic uncapacitated backlogged model. Subsequently, Levi *et al.* [38] proposed a 2-approximation algorithm for the capacitated backlogged model. Levi *et al.* [39] designed a 2-approximation algorithms for uncapacitated models with lost sales. Levi and Shi [40] provided a 3-approximation algorithm for the uncapacitated backlogged model with setup costs. Subsequently, Shi *et al.* [41] provided a 4-approximation algorithm for the capacitated backlogged problem with setup costs.

More recently, Truong [42] provided a 2-approximation algorithm for the stochastic inventory problem via a look-ahead (myopic) optimization approach. Tao and Zhou [43] designed a 2-approximation algorithm for stochastic inventory systems with remanufacturing. Chao *et al.* [44] proposed an approximation algorithm with a worst-case guarantee between 2 and 3 for perishable inventory systems. Subsequently, Chao *et al.* [45, 46] studied perishable inventory systems with capacity and setup cost, respectively. There are also recent works on designing approximation algorithms for multi-echelon inventory systems (e.g., Chu and Shen [47] for one-warehouse-multiretailer problems, Levi *et al.* [48] for serial inventory systems, and Levi and Shi [49] for joint replenishment problems). For the distribution-free or the black-box model, Levi *et al.* [50] also proposed an approximation scheme based on a sample average approximation approach for multiperiod stochastic inventory problems.

Other Core Stochastic Operations Management Models. The following list is by no means exhaustive.

- (a) *Scheduling.* Dean [51] in his doctoral thesis provided approximation algorithms for a broad class of stochastic

scheduling problems. He also conducted an exhaustive survey of this topic before his thesis. Shmoys and Sozio [52] designed approximation algorithms based on the approach of Charikar *et al.* [24] for two-stage stochastic scheduling problems, extending the results of Bar-Noy *et al.* [53].

- (b) *Vehicle Routing.* Gupta *et al.* [54] gave randomized approximation algorithms with factor $1 + \alpha$ for split-delivery vehicle routing problem with stochastic demands and $2 + \alpha$ for unsplit-delivery counterpart, where α is the best approximation guarantee for the traveling salesman problem. They also showed that the cyclic heuristic for split-delivery achieves a constant approximation ratio, thereby confirming the conjecture in Bertsimas [55]. More recently, Gørtz *et al.* [56] formulated the stochastic vehicle routing problem via a two-stage stochastic optimization with recourse and gave approximation results.
- (c) *Facility Location.* For the two-stage recourse model, Shmoys and Swamy [20] gave a $(3.225 + \epsilon)$ -approximation algorithm, whereas Gupta *et al.* [18] gave an 8.45-approximation algorithm in the black-box model with proportional cost, and Srinivasan [25] presented a 3.25-approximation algorithm for facility location in the polynomial scenario setting. So *et al.* [29] gave an 8-approximation algorithm for the risk-adjusted two-stage stochastic facility location problem. Shen *et al.* [57] studied a reliable facility location problem wherein some facilities are subject to failure from time to time and proposed a 4-approximation algorithm.
- (d) *Stochastic Network Design.* Gupta *et al.* [58, 59] gave LP rounding approximation algorithms for stochastic Steiner tree and stochastic network design problems. Krishnaswamy *et al.* [60] gave approximation algorithms for node-capacitated network design to minimize the energy consumption.

- (e) *Resource Allocation and Revenue Management*. Dean *et al.* [61] presented approximation algorithms for stochastic knapsack problems. Chan and Farias [62] gave a 2-approximation algorithm for multiperiod stochastic depletion problems. Geunes *et al.* [63] proposed a 1.582-approximation algorithm via LP rounding scheme for supply chain planning and logistics problems with market choice under demand uncertainties. Goyal *et al.* [64] devised a PTAS for the assortment planning problem under dynamic substitution and stochastic demand. Levi and Radovanoic [65] gave a 2-approximation algorithm for revenue management models with reusable resources. Subsequently, Levi and Shi [66] then extended the same results allowing for advanced reservations.

Many if not most of the core problems in operations management fall into the category of multistage stochastic optimization models. In particular, one has to make multiple, typically dependent decisions over time to optimize a certain objective function under uncertainty on how the system will evolve over the future time horizon. Unfortunately, it is often computationally intractable to find the exact optimal solutions for these fundamental and important models. Approximation algorithms seem to be the natural remedy for overcoming this prohibitive computing resource requirement.

Indeed, most of the heuristics and algorithms that have been proposed for operations management models were evaluated merely through computational experiments on randomly generated instances. This does not necessarily provide strong indications that the proposed heuristics are good in general, beyond the instances that were actually tested. In contrast, approximation algorithms have the advantage that they provide *a priori* and *a posteriori* guarantees on the quality of the solution produced by the algorithm. Moreover, the performance analysis provides insights on how to design algorithms that have good empirical performance, which

is in most cases significantly better than the worst-case performance guarantees.

Organization of the Article

The remainder of the article is organized as follows. In the section titled “Approximation Algorithms on Stochastic Inventory Models”, we discuss recent results on designing approximation algorithms for stochastic inventory systems. In the section titled “Approximation Algorithms on Revenue Management Models”, we present recent results on designing approximation algorithms for revenue management problems. The section titled “Conclusion and Future Directions” concludes our article and points out plausible avenues for future research.

APPROXIMATION ALGORITHMS ON STOCHASTIC INVENTORY MODELS

In this section, we focus our attention on designing approximation algorithms for stochastic inventory models that allow for generally correlated demand structures capturing demand seasonality and forecast updates. Table 1 shows the current available results on various stochastic inventory systems.

When decision makers want to incorporate any forecast update mechanisms, the future demands can be represented as a function of the current information set consisting of past realized demand information and some other possible exogenous information that is available to them. This unavoidably introduces correlations between the future demands, which make the dynamic programming formulation computationally intractable, as the state space grows exponentially fast. This is usually referred to as *the curse of dimensionality*. In this article, we present a single-echelon problem called the *stochastic lot-sizing problem*. The term lot-sizing captures the setup cost or interchangeably the fixed ordering cost whenever a strictly positive order is placed. We demonstrate how randomized approximation algorithms can be designed for this problem.

Model

We consider a finite planning horizon of T periods indexed $t = 1, \dots, T$. The demands over these periods are random variables, denoted by $D_1, \dots, D_T$, and the goal is to coordinate a sequence of orders over the planning horizon to satisfy these demands with minimum expected cost. As a general convention, from now on, we will refer to a random variable and its realization using capital- and lower-case letters.

In each period $t = 1, \dots, T$, four types of costs are incurred, a per-unit ordering cost c_t for ordering any number of units at the beginning of period t , a per-unit holding cost h_t for holding excess inventory from period t to $t + 1$, a per-unit backlogging penalty b_t that is incurred for each unsatisfied unit of demand at the end of period t , and a *fixed ordering cost* K that is incurred in each period with strictly positive ordering quantity. (It should be noted that our analysis remains valid for nonstationary K_t satisfying $\alpha K_{t+1} \leq K_t$, which is commonly assumed in the literature. Without loss of generality, we can assume that the discount factor $\alpha = 1$.) Unsatisfied units of demand are usually called *backorders*. Each unit of unsatisfied demand incurs a per-unit backlogging penalty cost b_t in each period t until it is satisfied. In addition, we consider a model with a lead time of L periods between the time an order is placed and the time at which it actually arrives. We assume that the lead time is a known integer L . We assume without loss of generality that the

discount factor is equal to 1 and that $c_t = 0$ and $h_t, b_t \geq 0$, for each t .

At the beginning of each period s , we observe what is called an *information set* denoted by f_s . The information set f_s contains all of the information that is available at the beginning of time period s . More specifically, the information set f_s consists of the realized demands $d_1, \dots, d_{s-1}$ over the interval $[1, s)$ and possibly some exogenous information. The information set f_s in period s is one specific realization in the set of all possible realizations of the random vector $F_s = (D_1, \dots, D_{s-1})$. The set of all possible realizations is denoted by $\mathcal{F}_s$. The observed information set f_s induces a given conditional joint distribution of the future demands $(D_s, \dots, D_T)$. For ease of notation, D_t will always denote the random demand in period t according to the conditional joint distribution in some period $s \leq t$, where it will be clear from the context to which period s it refers. The index t will be used to denote a general time period, and s will always refer to the current period. The only assumption on the demands is that for each $s = 1, \dots, T$, and each $f_s \in \mathcal{F}_s$, the conditional expectation $\mathbb{E}[D_t | f_s]$ is well defined and finite for each period $t \geq s$. In particular, we allow for nonstationary and correlation between the demands in different periods.

The traditional approach to study these models has been dynamic programming. Using the dynamic programming approach, it can be shown that *state-dependent* (s, S)

policies are optimal (see Zipkin [68]). However, the computational complexity of the resulting dynamic programs is very sensitive to the dimension of the sets $\mathcal{F}_s$. In particular, in many practical scenarios, these sets are of high dimension, which leads to dynamic programming formulations that are computationally intractable. In fact, it has been shown in Halman *et al.* [69] that this model is NP-hard, even for the relatively simple special case of independent discrete, finite support demands. In fact, for this special case, it is possible to construct a PTAS; that is, the problem can be approximated to an arbitrary degree of accuracy with a running time that depends on the degree of accuracy.

In addition, Guan and Miller [70, 71], Huang and Küçükyavuz [72], and Jiang and Guan [73] proposed exact and polynomial-time algorithms for the stochastic lot-sizing problem if the stochastic programming scenario tree is polynomially representable. These models allow for stochastic and correlated demands. However, the scenario tree in our model is exponentially large. Besides the exact (dynamic programming) approaches to stochastic lot-sizing problems, Guan *et al.* [74] and Zhang *et al.* [75] also proposed branch-and-cut methods to this class of problems.

Randomized Cost-Balancing Policies

In this section, we shall describe the *randomized cost-balancing policy* following Levi and Shi [40]. This policy is based on two major ideas: (i) *Marginal cost accounting scheme*. The standard dynamic programming approach directly assigns to the decision of how many units to order in each period only the expected holding and backlogging costs incurred in that period, although this decision might affect the costs in future periods. Instead, marginal cost accounting scheme assigns to the decision in each period *all* the expected costs that, once this decision is made, become unaffected by any decision made in future periods. These costs may still depend on future demands. (ii) *Randomizing cost balancing*. The idea of cost balancing was used in the past to construct heuristics with constant performance guarantees for deterministic inventory problems (Silver and

Meal [30]). The key observation in this model is that any policy in any period incurs potential expected costs because of *overordering* (namely, expected holding costs of carrying excess inventory) and *underordering* (namely, expected backlogging costs incurred when demand is not met on time). To address the nonlinearity induced by the fixed costs, a randomized decision rule is employed to balance the expected fixed ordering costs, holding costs, and backlogging costs, in each period. In particular, the order quantity in each period is decided based on a carefully designed randomized rule that chooses among various possible order quantities with carefully chosen probabilities.

Marginal Cost-Accounting Scheme. We first introduce a *marginal holding cost-accounting approach*. Without loss of generality, assume that the ordered supply units are consumed on *first-ordered, first-consumed basis*. The key observation under this assumption is that once an order is placed in some period, then the expected holding cost that the units just ordered will incur over the rest of the planning horizon is a function only of the realized demands over the rest of the horizon and not of any future orders. Hence, within each period, we can associate the overall expected holding cost that is incurred by the units ordered in this period over the entire horizon. We note that similar ideas of holding cost accounting were used previously in the context of models with continuous time, infinite horizon, and stationary (Poisson-distributed) demand (see the work of Axsäter and Lundell [76] and Axsäter [77]). More specifically, let x_s be the *inventory position* at the beginning of period s that captures the total sum of the physical *on-hand inventory* and the *outstanding orders* (placed in past periods but still on the way) minus the pending backlogged demand. Say now that q_s units were ordered in period s , and consider a future period $t \geq s + L$. Then, the holding cost incurred by the q_s units ordered in period s at the end of period t is $h_t(q_s - (D_{[s,t]} - x_s)^+)$, where $x^+ = \max(x, 0)$ and $D_{[s,t]} = \sum_{j=s}^t D_j$ is the cumulative demand over the interval $[s, t]$. Observe that if $D_{[s,t]} \leq x_s$, then none of the q_s units has been yet consumed. When

$D_{[s,t]}$ exceeds x_s , the q_s units are used to satisfy the demand until all of them are consumed. It follows that the total holding cost incurred by the q_s units ordered in period s over the entire horizon is equal to

$$H_s = H_s(Q_s) \triangleq \sum_{t=s+L}^T h_t(Q_s - (D_{[s,t]} - X_s)^+)^+. \quad (2)$$

Because X_s and Q_s are realized at the beginning of period s (whereas, x_s and q_s are the realizations of X_s and Q_s , respectively), then, as seen from the beginning of period s , this quantity depends only on future demands and not on any future decision.

In addition, in an uncapacitated model, the decision of how many units to order in each period affects the expected backlogging cost in only a single future period, namely, a lead time ahead. Now, let Π_s be backlogging cost incurred in period $s+L$, for each $s = 1-L, \dots, T-L$. In particular, it is straightforward to verify that

$$\Pi_s \triangleq b_{s+L}(D_{[s,s+L]} - (X_s + Q_s))^+, \quad (3)$$

where $D_j \triangleq 0$ with probability 1 for each $j \leq 0$. (Observe that the supply units captured by $X_s + Q_s$ will become available by time period $s+L$ and that no order placed after period s will arrive by time period $s+L$.)

Now, let $\mathcal{C}(P)$ be the cost of a feasible policy P and use the superscript P to relate the respective quantities to that policy. Clearly,

$$\begin{aligned} \mathcal{C}(P) \triangleq & \sum_{t=1-L}^0 \Pi_t^P + H_{(-\infty,0]} \\ & + \sum_{t=1}^{T-L} (K \cdot \mathbf{1}(Q_t^P > 0) + H_t^P + \Pi_t^P), \end{aligned} \quad (4)$$

where $H_{(-\infty,0]}$ denotes the total holding cost incurred by units ordered before period 1 (given as an input). We note that the first two expressions $\sum_{t=1-L}^0 \Pi_t^P$ and $H_{(-\infty,0]}$ are the same for any feasible policy and each realization of the demand, and, therefore, we will omit them. Because they are nonnegative, this will not affect our approximation results. In addition, observe that, without loss of generality, it can be assumed that $Q_t^P = H_t^P = 0$ for any policy P and each period

$t = T-L+1, \dots, T$, because nothing that is ordered in these periods can be used within the given planning horizon. We now can write

$$\mathcal{C}(P) \triangleq \sum_{t=1}^{T-L} (K \cdot \mathbf{1}(Q_t^P > 0) + H_t^P + \Pi_t^P). \quad (5)$$

The cost-accounting scheme in Equation (5) is marginal; that is, in each period, we account for all the expected costs that become unaffected by any future decision.

Randomized Cost-Balancing Policy. To describe the policy, we modify the definition of the information set f_t to also include the randomized decisions of the randomized balancing policy up to period $t-1$. Thus, given the information set f_t , the inventory position at the beginning of period t is known. However, the order quantity in period t is still *unknown* because the policy randomizes among various order quantities. We denote the randomized cost-balancing policy by RB. The decision in each period, whether to order and how much to order, is based on the following quantities.

- Compute the *balancing quantity* $\hat{q}_t$, which balances the expected marginal holding cost incurred by the units ordered against the expected backlogging cost in period $t+L$. That is, $\hat{q}_t$ uniquely solves

$$\mathbb{E}[H_t^{RB}(\hat{q}_t)|f_t] = \mathbb{E}[\Pi_t^{RB}(\hat{q}_t)|f_t] \triangleq \theta_t. \quad (6)$$

- Compute the *holding-cost- K quantity* $\tilde{q}_t$ that solves $\mathbb{E}[H_t^{RB}(\tilde{q}_t)|f_t] = K$, that is, $\tilde{q}_t$ is the order quantity that brings the expected marginal holding cost to K .
- Compute $\mathbb{E}[\Pi_t^{RB}(\tilde{q}_t)|f_t]$, that is., the expected backlogging cost if one orders $\tilde{q}_t$ units in period t .
- Compute $\mathbb{E}[\Pi_t^{RB}(0)|f_t]$, that is, the expected backlogging cost resulting from not ordering in period t .

On the basis of the above-mentioned quantities computed, the following randomized rule is used in each period t . Let P_t denote our ordering probability, which is *a priori*

random. With the observed information set f_t , the ordering probability $p_t = P_t|f_t$ in period t is defined differently in the two cases below.

Case I. If the balancing cost exceeds K , that is, $\theta_t \geq K$, the RB policy orders the balancing quantity $q_t^{RB} = \hat{q}_t$ with probability $p_t = 1$. The intuition is that when $\theta_t \geq K$, the fixed ordering cost K is less dominant compared to marginal holding and backlogging costs. Moreover, if the RB policy does not place an order, the conditional expected backlogging cost is potentially large. Thus, it is worthwhile to order the balancing quantity $q_t^{RB} = \hat{q}_t$ with probability $p_t = 1$.

Case II. If the balancing cost is less than K , that is, $\theta_t < K$, the RB policy orders the holding-cost- K quantity (i.e., $q_t^{RB} = \tilde{q}_t$) with probability p_t and nothing with probability $1 - p_t$. That is,

$$q_t^{RB} = \begin{cases} \tilde{q}_t, & \text{with probability } p_t \\ 0, & \text{with probability } 1 - p_t \end{cases}. \quad (7)$$

The probability p_t is computed by solving the following equation:

$$p_t K = p_t \cdot \mathbb{E}[\Pi_t^{RB}(\tilde{q}_t)|f_t] + (1 - p_t) \cdot \mathbb{E}[\Pi_t^{RB}(0)|f_t]. \quad (8)$$

The underlying reason behind the choice of this particular randomization in Equation (8) is that the policy perfectly balances the three types of costs, namely, the marginal holding cost, the marginal backlogging cost, and the fixed ordering cost associated with the period t . In particular, as we order the holding-cost- K quantity with probability p_t and nothing with probability $1 - p_t$, the conditional expected marginal holding cost in this case is

$$\begin{aligned} \mathbb{E}[H_t^{RB}(q_t^{RB})|f_t] &= p_t \mathbb{E}[H_t^{RB}(\tilde{q}_t)|f_t] \\ &+ (1 - p_t) \mathbb{E}[H_t^{RB}(0)|f_t] = p_t K. \end{aligned} \quad (9)$$

By the construction of p_t in Equation (8), the conditional expected backlogging cost is

$$\begin{aligned} \mathbb{E}[\Pi_t^{RB}(q_t^{RB})|f_t] &= p_t \mathbb{E}[\Pi_t^{RB}(\tilde{q}_t)|f_t] \\ &+ (1 - p_t) \mathbb{E}[\Pi_t^{RB}(0)|f_t] = p_t K. \end{aligned} \quad (10)$$

As p_t is the ordering probability in case II, the expected fixed ordering cost is $p_t K$. It can be shown that (8) has the following solution:

$$0 \leq p_t = \frac{\mathbb{E}[\Pi_t^{RB}(0)|f_t]}{K - \mathbb{E}[\Pi_t^{RB}(\tilde{q}_t)|f_t] + \mathbb{E}[\Pi_t^{RB}(0)|f_t]} < 1. \quad (11)$$

The inequalities in Equation (11) follows from the fact that $\theta_t < K$ and $\tilde{q}_t > \hat{q}_t$, which implies that $\mathbb{E}[\Pi_t^{RB}(\tilde{q}_t)|f_t] < \mathbb{E}[\Pi_t^{RB}(\hat{q}_t)|f_t] = \theta_t < K$.

Worst-Case Performance Analysis. To obtain a 3-approximation algorithm, one wishes to show that, on expectation, the cost of an optimal policy can “pay” for at least one-third of the expected cost of the randomized cost-balancing policy. The periods are decomposed into subsets in which we will define explicitly. For certain well-behaved subsets, we want to show that the holding and backlogging costs incurred by an optimal policy can pay for one-third of the cost incurred by the RB policy. The difficulty arises in analyzing the remaining subset of *problematic periods*, for which it is not a priori clear how to pay for their cost. These problematic periods are further partitioned into intervals defined by each pair of two consecutive orders placed by the optimal policy. It can be shown that the total expected cost incurred by the RB policy in problematic periods within each interval does not exceed $3K$. This implies that the fixed ordering cost incurred by an optimal policy can pay on expectation one-third of the cost incurred by the randomized cost-balancing policy in problematic periods. Let Z_t^{RB} be a random variable defined as

$$Z_t^{RB} \triangleq \mathbb{E}[H_t^{RB}(Q_t^{RB})|F_t] = \mathbb{E}[\Pi_t^{RB}(Q_t^{RB})|F_t]. \quad (12)$$

Note that Z_t^{RB} is a random variable that is realized with the information set in period t . Observe that by the construction of the RB policy, the random variable Z_t^{RB} is well defined because the expected marginal holding costs and the expected marginal backlogging costs are always balanced. That is, the conditional expected marginal holding cost is always equal to the conditional expected backlogging cost. In addition, the expected fixed ordering cost in period t is also Z_t^{RB}

by the construction of the algorithm, and, therefore, we have the following lemma:

Lemma 1 (Levi and Shi [40]) *Let $C(RB)$ be the total cost incurred by the RB policy. Then, we have*

$$\mathbb{E}[C(RB)] \leq 3 \cdot \sum_{t=1}^{T-L} \mathbb{E}[Z_t^{RB}]. \quad (13)$$

To complete the worst-case analysis, we would like to show that the expected cost of an optimal policy denoted by OPT is at least $\sum_{t=1}^{T-L} \mathbb{E}[Z_t^{RB}]$. This will be carried out by amortizing the cost of OPT against the cost of the RB policy. In particular, we shall show that, on expectation, OPT pays for a large fraction of the cost of the RB policy. In the subsequent analysis, we will use a random partition of periods $t = \{1, 2, \dots, T-L\}$ to the following sets: The set $\mathcal{T}_{1H} \triangleq \{t : \Theta_t \geq K \text{ and } Y_t^{OPT} > Y_t^{RB}\}$ consists of periods in which the balancing cost Θ_t exceeds K and the optimal policy had higher inventory position than that of the RB policy after ordering [recall that, if $\Theta_t \geq K$, then the RB policy orders the balancing quantity with probability 1 and the value Y_t^{RB} is known deterministically (i.e., realized) with F_t]. The set $\mathcal{T}_{1\pi} \triangleq \{t : \Theta_t \geq K \text{ and } Y_t^{OPT} \leq Y_t^{RB}\}$ consists of periods in which the balancing cost exceeds K and the inventory position of the optimal policy does not exceed that of the RB policy after ordering (see the above-mentioned comment regarding $\mathcal{T}_{1H}$). The set $\mathcal{T}_{2H} \triangleq \{t : \Theta_t < K \text{ and } Y_t^{OPT} \geq X_t^{RB} + \tilde{Q}_t^{RB}\}$ consists of periods in which the balancing cost is less than K , and in such periods, the inventory position of the RB policy after ordering would be either X_t^{RB} if no order was placed or $X_t^{RB} + \tilde{Q}_t^{RB}$ if the *holding-cost- K quantity* is ordered, depending on the randomized decision of the RB policy. However, the inventory position of OPT after ordering exceeds even $X_t^{RB} + \tilde{Q}_t^{RB}$. [Note again that the quantity $\tilde{Q}_t^{RB}$ is known deterministically (i.e., realized) with F_t .] Analogous to $\mathcal{T}_{2H}$, the set $\mathcal{T}_{2\pi} \triangleq \{t : \Theta_t < K \text{ and } X_t^{RB} \geq Y_t^{OPT}\}$ consists of periods in which the inventory position of OPT after ordering is below X_t^{RB} . The set $\mathcal{T}_{2M} \triangleq \{t : \Theta_t < K \text{ and } X_t^{RB} < Y_t^{OPT} < X_t^{RB} + \tilde{Q}_t^{RB}\}$ consists of

periods in which the balancing cost is less than K and the inventory position of OPT after ordering is within $(X_t^{RB}, X_t^{RB} + \tilde{Q}_t^{RB})$. Thus, whether the RB policy or OPT has more inventory depends on whether the RB policy placed an order. Note that the sets $(\mathcal{T}_{1H} - \mathcal{T}_{2M})$ are disjoint, and the union makes a complete set. Conditioning on f_t , it is already known which part of the partition period t belongs.

Next, we will explain that the total holding cost incurred by OPT is higher than the marginal holding cost incurred by the RB policy in periods that belong to $\mathcal{T}_{1H} \cup \mathcal{T}_{2H}$ and that the total backlogging cost incurred by OPT is higher than the backlogging cost incurred by the RB policy associated with periods within $\mathcal{T}_{1\pi} \cup \mathcal{T}_{2\pi}$.

Lemma 2 (Levi and Shi [40]) *The overall holding cost and backlogging cost incurred by OPT are denoted by H^{OPT} and Π^{OPT} , respectively. Then, we have, with probability 1,*

$$\begin{aligned} H^{OPT} &\geq \sum_t H_t^{RB} \cdot \mathbf{1}(t \in \mathcal{T}_{1H} \cup \mathcal{T}_{2H}), \Pi^{OPT} \\ &\geq \sum_t \Pi_t^{RB} \cdot \mathbf{1}(t \in \mathcal{T}_{1\pi} \cup \mathcal{T}_{2\pi}). \end{aligned} \quad (14)$$

The idea of Lemma 2 is as follows: In each period $t \in \mathcal{T}_{1H} \cup \mathcal{T}_{2H}$, the inequality $Y_t^{RB} < Y_t^{OPT}$ holds and implies that the Q_t^{RB} units ordered by the RB policy in period t have been ordered by OPT either in period t or even earlier. Thus, the holding cost they incur under OPT are higher than those incurred under the RB policy. On the other hand, in each period $t \in \mathcal{T}_{1\pi} \cup \mathcal{T}_{2\pi}$, the inequality $Y_t^{RB} \geq Y_t^{OPT}$ holds and implies that the backlogging incurred by OPT at the end of period $t+L$ will be higher than that of the RB in that period. We are still left with the problematic set $\mathcal{T}_{2M}$. Note that, in this particular set, whether the RB policy or OPT has more inventory depends on whether the RB policy placed an order. Fortunately, Lemma 3 shows that the fixed ordering costs incurred by OPT can cover the randomized balancing costs in $\mathcal{T}_{2M}$.

Lemma 3 (Levi and Shi [40]) *The expected randomized cost in set $\mathcal{T}_{2M}$ is less than the*

total expected fixed ordering cost incurred by OPT , that is,

$$\begin{aligned} & \mathbb{E} \left[\sum_t Z_t^{RB} \cdot \mathbf{1}(t \in \mathcal{T}_{2M}) \right] \\ & \leq \mathbb{E} \left[\sum_{t=1}^{T-L} K \cdot \mathbf{1}(Q_t^{OPT} > 0) \right]. \end{aligned} \quad (15)$$

As an immediate consequence of Lemmas 2 and 3, we obtain the following lemma and theorem.

Lemma 4 (Levi and Shi [40]) *Let $C(OPT)$ be the total cost incurred by the cost-balancing policy RB . Then, we have,*

$$\mathbb{E}[C(OPT)] \geq \sum_{t=1}^{T-L} \mathbb{E}[Z_t^{RB}]. \quad (16)$$

Theorem 2 (Levi and Shi [40]) *For each instance of the stochastic lot-sizing problem, the expected cost of the randomized cost-balancing policy RB is at most three times the expected cost of an optimal policy OPT , that is,*

$$\mathbb{E}[C(RB)] \leq 3 \cdot \mathbb{E}[C(OPT)]. \quad (17)$$

Some Remarks and Future Directions

The worst-case analysis suggests that the theoretical worst-case performance bound is three. However, extensive computational experiments (Levi and Shi [40]) show that the randomized cost-balancing policy performs significantly better than the worst-case guarantee, in most cases within 5% of optimum.

It has been shown (see, Levi and Shi [40]) that one can consider parametric versions of these policies and use known lower and upper bounds on the optimal ordering levels to devise more sophisticated policies with better empirical (typical) performance, some of which still admit worst-case analysis. The parameterization of these policies is motivated by the fact that, in the context of worst-case analysis, one wishes to choose policies

that “protect” against all possible instances, whereas per a given (known) instance, it is possible to choose the parameters of the policy optimally with respect to that instance. This naturally leads to improved empirical performance.

Besides the summary of current results shown in Table 1, designing approximation algorithms to stochastic assemble-to-order systems, stochastic one-warehouse multiretailer problems, stochastic joint inventory, and pricing models, the stochastic perishable inventory with depletion decisions remains an open challenge and will definitely require novel ideas and techniques. Another important future research direction is to study the performance of cost-balancing policies under various assumptions on the underlying demand distributions. As much as it is powerful to establish general worst-case analysis, it is equally important to refine this analysis to various parametric regimes of the underlying demand distributions and other key parameters of the problem. We call this *parametric worst-case analysis*.

APPROXIMATION ALGORITHMS ON REVENUE MANAGEMENT MODELS

In this section, we consider a class of revenue management problems that arise in systems with *reusable resources* and *advanced reservations*. This work is motivated by both traditional and emerging application domains, such as hotel room management, car rental management, and workforce management. For instance, in hotel industries, customers make requests to book a room in the future for a specified number of days. This is called *advanced reservation*. Rooms are allocated to customers based on their requests, and after one customer used a room, it becomes available to serve other customers. One of the major issues in these systems is how to manage capacitated pool of reusable resources over time in a dynamic environment with many uncertainties.

Model

We consider revenue management problems of a single pool of reusable resources used to

serve multiple classes of customers through advanced reservations. There is a single pool of resources of integer capacity $C < \infty$ that is used to satisfy the demands of M different classes of customers. The customers of each class $k = 1, \dots, M$, arrive according to an independent Poisson process with respective rate λ_k . Each class- k customer requests to reserve one unit of the capacity for a specified *service time interval* in the future.

Let D_k be the reservation distribution of a class- k customer and S_k be the respective service distribution with mean μ_k . We assume that they are nonnegative, discrete, and bounded. In particular, upon an arrival of a class- k customer at some random time t , the customer requests to reserve the service time interval $[t + d, t + d + s]$, where d is distributed according to D_k and s according to S_k . Note that D_k and S_k are independent of the arrival process and between customers; however, per customer, D_k and S_k can be correlated. (We assume that both D_k and S_k are finite discrete distributions.) During the time a customer is served (i.e., $[t + d, t + d + s]$), the requested unit cannot be used by any other customer; after the service is over, the unit becomes available again to serve other customers. If the resource is reserved, the customer pays a class-specific rate of r_k dollars per unit of service time. The resource can be reserved for an arriving customer only if on arrival there is at least one unit of capacity that is available (i.e., not reserved) throughout the entire requested interval $[t + d, t + d + s]$. Specifically, a customer's request can be satisfied if the maximum number of already reserved resources throughout the requested service interval is smaller than the capacity C . However, customers can be rejected even if there is available capacity. Rejecting a customer now possibly enables serving more profitable customers in the future. Customers whose requests are not reserved upon arrival are *lost* and leave the system. The goal is to find a feasible admission policy that maximizes the expected long-run average revenue. Specifically, if $\mathcal{R}_\pi(T)$ denotes the revenue achieved by policy π over the interval $[0, T]$, then the expected long-run average revenue of π is defined

as $\mathcal{R}(\pi) \triangleq \liminf_{T \rightarrow \infty} (\mathbb{E}[\mathcal{R}_\pi(T)]/T)$, where the expectation is taken with respect to the probability measure induced by π .

Like many stochastic optimization models, one can formulate this problem using dynamic programming approach. However, even in special cases (e.g., no advanced reservations allowed and with exponentially distributed service times), the resulting dynamic programs are computationally intractable because of the *curse of dimensionality*.

An LP-Based Approach

In this section, we describe a simple LP that provides an upper bound on the achievable expected long-run average revenue. The LP conceptually resembles the one used by Levi and Radovanovic [65], Key [78], and Iyengar and Sigman [79], who studied models without advanced reservations. It is also similar in spirit to the one used by Adelman [80] in the queueing networks framework with unit resource requirements again without advanced reservations. We shall show how to use the optimal solution of the LP to construct a simple admission control policy that is called *class selection policy* (CSP).

At any point of time t , the state of the system is specified by the entire booking profile consisting of the class, reservation, and service information of each customer in the booking system as well as the customers currently served. Without loss of generality, we restrict attention to *state-dependent policies*. Note that each state-dependent policy induces a Markov process over the state space, and one can show that the induced Markov process has a unique stationary distribution, which is ergodic. The detailed technical proof can be found in Levi and Shi [66] following the arguments in Sevastyanov [81] and Lu and Radovanovic [82]. The key idea is to find a *fixed* auxiliary probability distribution that can be scaled (by positive constants) to lower and upper bounds of the transitional probability in the underlying Markov chain. This auxiliary probability distribution can be readily found if the state space is compact (which is true in our model).

As any state-dependent policy induces a Markov process on the state space of the

system that is ergodic, for a given state-dependent policy π , there exists a long-run stationary probability α_{ijk}^π for accepting a class- k customer who wishes to start service in i units of time for j units of time, which is equal to the long-run proportion of accepted customers of this type while running the policy π . In other words, any state-dependent policy π is associated with the stationary probabilities α_{ijk}^π for all possible reservation time i , service time j , and class k . Let $\lambda_{ijk} \triangleq \lambda_k \mathbb{P}(D_k = i, S_k = j)$ be the arrival rate of class- k customers with reservation time i and service time j . Therefore, the mean arrival rate of accepted class- k customers with reservation time i and service time j is $\alpha_{ijk}^\pi \lambda_{ijk}$. By Little's Law and PASTA (see, e.g., Gallager [83]), the expected number of class- k customers with reservation time i and service time j being served in the system under π is $\alpha_{ijk}^\pi \lambda_{ijk} j$. It follows that, under π , the expected long-run average number of resource units being used to serve customers can be expressed as $\sum_{k=1}^M \sum_{i,j} \alpha_{ijk}^\pi \lambda_{ijk} j$. This gives rise to the following *knapsack* LP:

$$\max_{\alpha_{ijk}} \sum_{k=1}^M \sum_{i,j} r_k \alpha_{ijk}^\pi \lambda_{ijk} j, \quad (18)$$

$$\text{s.t. } \sum_{k=1}^M \sum_{i,j} \alpha_{ijk}^\pi \lambda_{ijk} j \leq C, \quad (19)$$

$$0 \leq \alpha_{ijk}^\pi \leq 1, \quad \forall i, j, k. \quad (20)$$

Note that, for each feasible state-dependent policy π , the vector $\alpha^\pi = \{\alpha_{ijk}^\pi\}$ is a feasible solution for the LP with objective value equal to the expected long-run average revenue of policy π . In fact, the LP enforces the capacity constraint (19) of the system only in expectation, whereas in the original problem, this constraint has to hold, for each sample path. It follows that the LP relaxes the original problem and provides an upper bound on the best-obtained expected long-run average revenue. The LP can be solved optimally by applying the following greedy rule: Without loss of generality, assume that classes are renumbered such that $r_1 \geq r_2 \geq \dots \geq r_M$. Then, for each $k = 1, \dots, M$, we sequentially

set $\alpha_{ijk} = 1$ for all i and j as long as constraint (19) is satisfied. If there exists a class $M' \leq M$ such that

$$C = (1 - \gamma) \sum_{k=1}^{M'-1} \sum_{i,j} \lambda_{ijk} j + \gamma \sum_{k=1}^{M'} \sum_{i,j} \lambda_{ijk} j,$$

for some $\gamma \in (0, 1)$, we set $\alpha_{ijM'} = \gamma$ for all i and j . Note that, for each class k , the values of α_{ijk} are all equal regardless of i and j . We abuse the notation and drop the subscripts i and j of α_{ijk} . Then, the optimal solution reduces to: for $k = 1, \dots, M' - 1$, $\alpha_k = 1$; $\alpha_{M'} = \gamma$; and for $k = M' + 1, \dots, M$, we have $\alpha_k = 0$.

Next, we shall use the optimal solution of the knapsack LP to construct a very simple admission policy. Let $\alpha^* = \{\alpha_k^*\}$ be the optimal solution of the knapsack LP. We propose a simple policy that is called *CSP*. Consider an arrival of a class- k customer ($k = 1, \dots, M$). For each $k = 1, \dots, M' - 1$, *accept* the customer on arrival (regardless of the reservation time and the service time) as long as there is sufficient unreserved capacity throughout the requested service interval. If $k = M'$, *accept* the customer with probability γ (regardless of the reservation time and the service time) and as long as there is sufficient unreserved capacity throughout the requested service interval. For each $k = M' + 1, \dots, M$, *reject*.

The CSP has a very simple structure. It always admits customers from the classes for which the corresponding value α_k^* in the optimal LP solution equals to one as long as capacity permits. It never admits customers from classes for which the corresponding value α_k^* equals to zero, and it flips a coin for the possibly one class with fractional value $\alpha_{M'}^* = \gamma$. The CSP is conceptually very intuitive; in that, it splits the classes into profitable and nonprofitable that should be ignored. In fact, we can assume, without loss of generality, that there is no fractional variable in the optimal solution α^* , that is, for each $k = 1, \dots, M'$, $\alpha_k^* = 1$. (If $\alpha_{M'}^* = \gamma$ is fractional, we think of class M' as having an arrival rate $\lambda'_{M'} = \gamma \lambda_{M'}$ and then eliminate the fractional variable from α^* .)

Worst-Case Performance Analysis

In this section, we discuss performance analysis of the CSP under models with advanced reservations. The CSP induces a well-structured stochastic process called *loss networks* with advanced reservations (i.e., a $M/G/C/C$ loss system with advanced reservations). Each class $k = 1, \dots, M$ induces a Poisson arrival stream with respective rate $\alpha_k^* \lambda_k$, $1 \leq k \leq M$. Thus, for each class k with $\alpha_k^* = 1$, the arrival process is identical to the original process, and each class k with $\alpha_k^* = 0$ can be ignored. For each class $k = 1, \dots, M'$, let S_k and D_k be the service and reservation distributions of class- k customers, respectively. We want to characterize the long-run *blocking probability* of class- k customers with reservation time i and service time j under the CSP, that is, the stationary probability that a class- k customer with reservation time i and service time j arrives at a random time to the system and is rejected by the CSP because there is no available capacity at some point within the requested service interval. For each $k = 1, \dots, M'$, let Q_{ijk} be the stationary probability of blocking a class- k customers with reservation time i and service time j under the CSP. As the corresponding stochastic process is ergodic, Q_{ijk} is well defined. Thus, the expected long-run average revenue of the CSP can be expressed as $\sum_{k=1}^{M'} \sum_{i,j} r_k \lambda_{ijk} j (1 - Q_{ijk})$. However, $\sum_{k=1}^{M'} \sum_{i,j} r_k \lambda_{ijk} j$ is the optimal value of the LP, which is an upper bound on the best-achievable expected long-run average revenue, denoted by $\mathcal{R}(OPT)$. Thus, a key aspect of the performance analysis of the CSP is to obtain an upper bound on the probabilities Q_{ijk} 's. More specifically, if $1 - Q_{ijk} \geq \xi$, for each i, j , and k , it follows that

$$\begin{aligned} \mathcal{R}(CSP) &= \sum_{k=1}^{M'} \sum_{i,j} r_k \lambda_{ijk} j (1 - Q_{ijk}) \\ &\geq \sum_{k=1}^{M'} \sum_{i,j} r_k \lambda_{ijk} j \xi \geq \xi \mathcal{R}(OPT). \end{aligned} \quad (21)$$

We want to upper bound probabilities Q_{ijk} 's and analyze their asymptotic behavior under the Halfin–Whitt regime. The *traffic*

intensity $\rho \triangleq \sum_{k=1}^M \sum_{i,j} \lambda_{ijk} j = \sum_{k=1}^M \lambda_k \mu_k$. Under the Halfin–Whitt regime, the capacity C and the arrival rates λ_k as well as the traffic intensity ρ are scaled together to infinity while keeping the service and the reservation distributions fixed (i.e., $C = \rho + \beta \sqrt{\rho} + o(\sqrt{\rho}) \rightarrow \infty$, for some positive spare capacity parameter β).

Theorem 3 (Levi and Shi [66]) *Consider the revenue management model with a single pool of capacitated reusable resources and advanced reservations under the CSP. Let $\Phi(\cdot)$ be the cumulative density function of a standard normal. Then:*

- (a) *For each k and j , the blocking probability Q_{ijk} has the following asymptotic upper bound:*

$$\lim_{\rho \rightarrow \infty} Q_{ijk} \leq \Phi(-\beta); \quad \lim_{\rho \rightarrow \infty} Q_{ijk} = 0, \quad \forall i \geq 1,$$

where $\beta > 0$ is the spare capacity parameter in the Halfin–Whitt regime.

- (b) *The CSP is guaranteed to obtain at least 0.5 of the optimal expected long-run average revenue in the Halfin–Whitt heavy-traffic limit.*

The upper bound on the blocking probability is obtained by considering a counterpart system with infinite capacity, where all customers are admitted into an $M/G/\infty$ system with advanced reservations. The detailed stochastic analysis of this loss queueing system with advanced reservations falls out of scope of this article, and we refer interested readers to Levi and Shi [66].

Some Remarks and Future Directions

There are also several plausible extensions into pricing models. An interesting direction is to study both the static and dynamic pricing model of reusable resources with advanced reservations. The static pricing model allows the arrival rates being affected by prices. Specifically, consider a two-stage decision. At the first stage, we set the

respective prices $r_1, \dots, r_M$ for each class. This determines the respective arrival rates $\lambda_1(r_1), \dots, \lambda_M(r_M)$. (The rate of class- i customers is affected only by price r_i .) Then, given the arrival rates, we wish to find the optimal admission policy that maximizes the expected long-run revenue rate. We may assume that $\lambda_i(r_i)$ is nonnegative, differentiable, and decreasing in r_i for each $1 \leq i \leq M$. One might construct an upper bound on the achievable expected long-run revenue rate through a nonlinear program and then use it to construct a similar policy with the same performance guarantees. In the dynamic pricing model, consider a single-class time-homogenous Poisson arrival process with rate λ . Each customer's reservation and service time are drawn from D and S , respectively. The system offers a price from a fixed price menu $[r_1, \dots, r_n]$ to an arriving customer with d and s , depending on the current state. The state is characterized by the booking profile, d and s . A reservation price distribution R has to be specified, that is, the customer only accepts the offer if the price offered falls below the reservation price. One might construct a new linear program to obtain provably near-optimal randomized policies.

CONCLUSION AND FUTURE DIRECTIONS

Mathematical programming techniques have been used extensively to obtain relaxations and provably near-optimal approximation algorithms for deterministic combinatorial optimization problems (see, Ausiello *et al.* [1], Vazirani [2], and Williamson and Shmoys [3]). As mentioned in our literature review, more recent work has extended these approaches and/or developed novel techniques for two-stage and multistage stochastic optimization problems. These powerful techniques were developed for a wide range of combinatorial optimization problems and could be potentially applied to many core operation management models. We would like to point out some plausible research avenues for future research: (i) *Data-driven models*. Many of the underlying stochastic applications in operations management often involve correlated data (e.g.,

the demands in stochastic inventory control problems are often correlated over periods because of economic and/or seasonal factors). The decision makers may not know the demand distributions exactly and can only rely on collected (unbiased) sampling data. The sampling-based framework developed by Gupta *et al.* [19] and Swamy and Shmoys [23] could be applied to many distribution-free operations management models. These black-box models are desirable in that they allow one to specify distributions with exponentially many scenarios and correlation in a compact way that makes it reasonable to talk about polynomial-time algorithms. (ii) *Models with risk*. The multistage stochastic model measures the expected cost associated with each stage; however, often in applications, one is also interested in the risk associated with each stage decisions, where risk is some measure of the variability in the random cost incurred in later stages. Gupta *et al.* [58] considered the use of budgets that bound the cost of each scenario, as a means of guarding against risk. It would be interesting to explore stochastic operations management models that incorporate risk. One may also consider designing approximation algorithms for the robust variants of these models. (iii) *Models with endogenous uncertainty*. Another interesting and important research avenue, which brings us closer to Markov decision processes, is to investigate problems where the uncertainty is affected by the decisions taken. For instance, in stochastic scheduling problems, the scheduling decisions interact with the evolution of the random job sizes, especially in a preemptive environment. Another salient example is the joint inventory and pricing problem where the pricing decisions influence the demands.

ACKNOWLEDGMENT

We are very grateful to the Topical Editor Simge Küçükyavuz and two anonymous referees for their detailed comments and suggestions, which have helped to significantly improve both the content and the exposition of this article. The research of Cong Shi is

partially supported by NSF grants CMMI-1362619 and CMMI-1451078.

ASSESSING PROBABILITY DISTRIBUTIONS FROM DATA

VICTOR RICHMOND R. JOSE
McDonough School of Business,
Georgetown University,
Washington, D.C.

INTRODUCTION

The task of assessing probabilities for uncertain events can be cognitively challenging even for the most skilled forecasters. This is most evident when one has limited prior experience with such events. The presence of data, however, can ease the burden on the decision maker by providing a good starting point for understanding the nature of the uncertainty, and such data hopefully would lead to accurate and reliable assessments.

In many cases, it is almost impossible to find information directly related to the uncertainty of concern. Some related data, however, are typically available that could be used to improve our understanding of the uncertainty.

For example, consider an engineer who is studying the failure time of a certain component. She is mainly concerned about whether this component will last until some ordered spares arrive, in order to prevent an disruption in the company's operations. She may study data on the same component or a closely related product for which information is available. This information may be used to generate a probability assessment for this component since it seems to be a reasonable assumption that the life of this component would be similar to that of other identical or similarly designed items.

On the other hand, consider an insurance company which routinely assesses the likelihood that a customer would be involved in a motor vehicle accident. It would be a realistic assumption to say that based on certain demographics such as age, occupation,

and driving experience, some individuals are more likely than others to be involved in an accident. Here, the related information can be used to help predict whether or not the customer would be involved in an accident say, in the next year.

In these examples, data become useful in the probability assessment process. In the engineering example, assessments can be made by using a "historical approach," that is, probabilities are assigned to events based on the assumption that past information is representative of current and future behavior. It works on the premise that the earlier events are drawn from a common distribution or process and that the event being assessed will follow as well. In the insurance example, however, it may no longer be plausible to assume that the chance of a particular individual getting into a motor vehicle accident is a simple random draw from the accident history of everyone in the population. Here, additional explanatory variables are used to make inferences about the event probability.

ASSESSMENTS USING HISTORICAL DATA

In the historical data approach, a probability assessment is made by generating a distribution based on past information and using this for analysis related to the uncertainty of interest. Framed as such, a large literature in statistics is available and has been devoted to address this problem.

Parametric Approach

Traditionally, constructing probability distributions from data often starts by considering a subset of probability measures that are indexed by some parameter $\theta \in \mathbb{R}^n$. By considering functions characterized by this parameter θ , the assessment task is somewhat easier since the focus is then simply on estimating appropriate values for θ .

Choosing a Model. Often, problems can be approached in many different ways and

choosing an appropriate model can be somewhat confusing. Though there is no acid test to clearly determine which distribution or parametric family is appropriate in every occasion, research [1] suggests that considering simple questionnaires about the uncertainty (such as the one listed below) can be helpful in limiting the set of distributions that we need to consider.

1. *Nature of the Sample Space.* Is the random variable discrete, continuous or mixed (i.e., can it take only discrete values, is it continuous over some interval(s) or both)? Are we dealing with a univariate or multivariate distribution?
2. *Bounds.* Is the range of values bounded above? Or below? If so, what are reasonable upper and lower bounds?
3. *Shape.* Is the distribution symmetric? If it is skewed, in which direction is it skewed?
4. *Concentration.* What range of values is of primary interest to us? Is the modeling of the tails critical? Is the distribution unimodal? Or multimodal?
5. *Underlying Process and Dependencies.* Is there an underlying process? Do we expect the variable to be dependent on other variables? Are the variables correlated? Are other forms of dependencies known?

Despite the fact that questionnaires like this one can be used to limit the parametric families that we should consider, it often does not single out a particular parametric family. Often, we still have to choose among several distributions.

Working with a Model. For each of the models which we might consider, the next task for the decision maker is to generate the probability assessments that he or she needs. Consider our engineering example: suppose the records show that the last 15 units of the same component used in the plant lasted 12, 14, 15, 6, 9, 10, 11, 12, 14, 13, 13, 10, 14, 9, and 18 days. If the spares are scheduled to arrive in 10 days, then we can use this to estimate the probability that there will be a disruption.

If we assume that the data we have observed comes from independent draws from a common distribution with the same probability of lasting less than 10 days, then we can say that a binomial distribution (i.e., $f(x) = \theta^x(1 - \theta)^{n-x}$) might be appropriate for this. Having decided on a parametric model would then limit the problem to estimating an appropriate value for θ .

Suppose that over a period of time or a series of experiments, you were able to collect a random sample $X_1, \dots, X_n$ coming from a distribution function $F(x; \theta)$, where θ is an unknown parameter belonging to some set $\Theta \subset \mathbb{R}^m (m \geq 1)$. There are many ways to estimate θ . Perhaps the most commonly used approach used today is the maximum likelihood (ML) approach. Under this method, the data observed is assumed to be generated by some joint distribution L (characterized by the parameter θ) called a *likelihood function*

$$L(\theta) = f(x_1, \dots, x_n | \theta). \quad (1)$$

The estimation is then made by finding the $\hat{\theta}$, which maximizes the value of Equation (1), that is,

$$\hat{\theta} = \arg \max_{\theta \in \Theta} L(\theta). \quad (2)$$

The estimate in Equation (2) can be interpreted as the parameter that gives the highest probability (or the one that makes it “most likely”) that the data comes from the said process. A large literature has shown many interesting and useful statistical properties for the ML estimator, making it desirable to many researchers and practitioners. However, one challenge still encountered in this approach is that solving Equation (2) for certain functions can be computationally difficult.

Going back to our example, it can be verified that the ML approach would yield an estimate for θ of $12/15 = 80\%$. Intuitively, this makes sense since 3 instances of the 15 were less than the delivery time of 10 days. Alternative estimation techniques which may yield significantly different results, are also available. Lehmann and Casella [2] provide a detailed discussion on different statistical estimation techniques.

Naturally, an alternative model could also make the estimates significantly different. For example, if we assume that the lifetimes of the component follow say, a normal distribution, then the estimate for the mean and standard deviation using a moment-matching approach would be 12 and 2.95 respectively. This would mean that the probability that the component survives before the spare arrives would be $\mathbb{P}(\text{Component Life} \geq 10) = \mathbb{P}(Z \geq -0.678) = 75.1\%$.

An alternative approach to solving for point estimates is computing for the posterior distribution of the parameter θ and using this information to generate an estimate for the parameter. Given prior information on θ encoded in the distribution $f(\theta)$, Bayes' rule allows us to compute the posterior distribution of θ as follows:

$$f(\theta|\mathbf{x}) = \frac{f(x_1, \dots, x_n|\theta) f(\theta)}{\int f(x_1, \dots, x_n|\theta) f(\theta) d\theta}. \quad (3)$$

Typically, in many instances where no information on θ is available, the statistical literature often relies on the use of noninformative (or diffuse) priors. Once a posterior distribution is attained, we can then use this for analysis. Retrospectively, we can also use this to make probabilistic statements about the uncertainty. The posterior mean of θ could be used as an estimate for θ , similar to what the ML approach tries to achieve. Other statistics (such as the median or other specific quantiles) could be used as well, depending on the problem. Compared to the earlier approach, this Bayesian treatment is a more careful analysis about the event uncertainty since the inherent uncertainties in θ is incorporated in the analysis through the prior distribution $f(\theta)$.

Selecting among Models. If only one model is considered appropriate, then there is no ambiguity in which probability estimate to use. However, when multiple models are considered, we often have to choose which one should be used and reported.

The typical approach in practice is to compare models based on their fit with the empirical data. Models are ranked using goodness-of-fit statistics. Some commonly

used statistics include Pearson's chi-squared (χ^2), Kolmogorov–Smirnov (KS), and Anderson–Darling (AD). D'Agostino and Stephens [3] provide a more detailed treatise on this subject.

Current statistical softwares have the ability to fit data into certain parametric families. In addition, users have the option of ranking the distributions based on fit using some common goodness-of-fit statistics. For example, Crystal Ball, a commonly used Monte Carlo simulation package, estimates parameters for distributions using an ML approach and users have the option to rank distributions based on either the χ^2 , KS, or AD statistic. Figure 1 shows a sample output generated by Crystal Ball for a small financial data set.

For these data-fitting techniques, one important issue that often happens in practice is dealing with small data sets. Research [4] has shown that for several well-known distributions, small differences in the estimates have a large effect on decision and risk analysis studies, especially when the uncertainty has a high relative standard deviation. Extra caution is needed when relying on assessments and analysis that are generated from such small data sets.

Nonparametric Approach

Once in a while, an individual may not have sufficient information to select a class of parametric families to use. In these cases, making certain assumptions on the functional form of the distribution might lead to large errors instead of improvements in the model. In a risk analysis study [5], it was shown that incorrect substitutions in functional forms of probability distributions generated errors that can grow by a “factor on the order of $\sqrt{n}$ for a data set of n measurements”.

An alternative to forcing a choice for a parametric model is to allow the empirical data to determine the distribution on its own. In this nonparametric approach, the empirical distribution is used as the probability distribution in the analysis. This practice is commonly done in Monte Carlo simulation for determining some distribution when none of the standard distributions used seem to

Figure 1. Data-fitting option of Crystal Ball.

Figure 2. Using empirical distributions in a Monte Carlo setting.

be appropriate. Many Monte Carlo and statistical software packages now allow users to use empirical distributions in their analysis. Figure 2 shows the tool in Crystal Ball that could be used to create a custom distribution.

Though the freedom from choosing a parametric family seems to be a better alternative, the nonparametric approach has its own setback. The main disadvantage of this approach is that the quality and reliability of the analysis exponentially decreases as the number of data points drop. To a lesser extent, tractability may also provide some

problems but with the presence of modern computing this is not a big issue unless the dimension or size of the problem is large.

ASSESSMENTS USING EXPLANATORY VARIABLES

A different and equally valid approach in using data to assess probability distributions is to use historical and current information to predict certain events. For example, consider a firm that has decided to provide a new type of small short-term loans to its customers.

In this case, one useful assessment question that might be asked by this firm is how likely is it that an individual will default a loan if one gets approved.

In this case, historical information on default rates may not be as useful since customers with different backgrounds and profiles may not be likely to default their loans at the same rate. If there is historical data on loans of a similar type, then some analyses could be done to estimate the probability that an individual would default. In particular, information such as age, household income, level of education, amount of credit card debt, and current credit rating score might be useful in predicting the default rates for each individual applicant.

Tools from Categorical Data Analysis

One class of models that could be used to analyze explanatory variables is called *discrete choice models*, which are models that predict what category an uncertain event would materialize as a function of any number of variables that are believed to have an influence on the event.

Binary Models. Consider a Bernoulli random variable Y_i , which depends on a set of explanatory variables $(X_{i1}, \dots, X_{in})$. An initial model that could be considered is a *linear probability model*, which tries to linearly model the probability through the explanatory variables, that is,

$$p_i \equiv E(Y_i) = \beta_0 + \beta_1 X_{i1} + \dots + \beta_n X_{in}. \quad (4)$$

Two problems are typical in an approach such as this. First, the estimate that you might get may fall outside the interval $[0,1]$.

The other issue is that the event probability may not be linearly related to the explanatory variable. Typically, you may expect that as you go to the extremities, changes in the probability would start to become smaller. An alternative approach which addresses these issues and has also been popular in the literature is *logistic regression*.

Logistic regressions are models that fit the log-odds ratio (or “logit”) of a binomial random variable as a linear function of the predictor variables $\{X_{ij}\}_{j=1}^n$, that is,

$$\begin{aligned} \text{logit}(p_i) &= \ln\left(\frac{p_i}{1-p_i}\right) \\ &= \beta_0 + \beta_1 X_{i1} + \dots + \beta_n X_{in}. \end{aligned} \quad (5)$$

Equation (5) is equivalent to

$$p_i = \mathbb{P}(Y_i = 1) = \frac{1}{1 + \exp^{-(\beta_0 + \beta_1 X_{i1} + \dots + \beta_n X_{in})}}. \quad (6)$$

The term *logistic* comes from the fact that Equation (6) is similar in form to a logistic curve/function which has the form $f(x) = (1 + \exp(-x))^{-1}$. Figure 3 shows an example comparing a linear probability model with a logistic regression.

To solve for the coefficients in a logistic model, ML estimation is performed. In certain instances the ML estimation procedure can be computationally tedious, especially for

Figure 3. A comparison of the linear probability and logit models.

large problems. However, standard statistical software such as Stata, SAS, and SPSS now have a logistic regression tool built into their standard packages; that does these computations quickly and efficiently.

Multinomial Models. In cases where there are more than two possible states or categories, the binary model can be extended to the multinomial case. If Y_i can take on the values $\{1, 2, \dots, m\}$, then we can write the logit equations as

$$\text{logit}(p_{ij}) = \beta_{0j} + \beta_{1j}X_{i1} + \dots + \beta_{nj}X_{in}, \quad (7)$$

for $j \neq i$. Since we also know that $\sum_j p_{ij} = 1$, we only need $m - 1$ equations for Equation (7). Hence, one category (WLOG say state 1) is typically chosen to be the reference state; that is, the log-odds ratio is always compared to the first state making things easier to compare or mathematically,

$$\text{logit}(p_{ij}) = \ln \left[\frac{\mathbb{P}(Y_i = j)}{\mathbb{P}(Y_i = 1)} \right]. \quad (8)$$

Then, Equation (7) can be rewritten as

$$\begin{aligned} p_{i1} &= \mathbb{P}(Y_i = 1) \\ &= \frac{1}{1 + \sum_{k=2}^m \exp(\beta_{0k} + \beta_{1k}X_{i1} + \dots + \beta_{nk}X_{in})}, \end{aligned} \quad (9)$$

$$\begin{aligned} p_{ij} &= \mathbb{P}(Y_i = j) \\ &= \frac{\exp(\beta_{0j} + \beta_{1j}X_{i1} + \dots + \beta_{nj}X_{in})}{1 + \sum_{k=2}^m \exp(\beta_{0k} + \beta_{1k}X_{i1} + \dots + \beta_{nk}X_{in})} \\ &\text{for } j \neq 1. \end{aligned} \quad (10)$$

Again, many software packages available today incorporate a multinomial logistic regression tool. In addition, other multinomial logistic models (ordered state space models, conditional logistic models) are available in these packages. An excellent discussion of these more sophisticated models is provided in Refs 6 and 7.

Tools from Time Series Models and Forecasting

Alternatively, we can also use some inferential techniques to generate probability assessments over continuous intervals. Consider a fashion retailer who is trying to provide probabilities for sales for the next few quarters. Given the presence of past data, projections for future revenue streams can be generated say, by using some time series forecasting technique that could be used to provide a predictive distribution for future sales. Figure 4 provides an example of a data series where seasonal patterns are quite evident; draws from historical values might be misleading because of the growth trend that has been experienced by this firm.

Moreover, one may be interested in using other predictors outside the historical data for making predictions. Generalized linear models might be used to predict say, the sales, using other variables such as the advertising

Figure 4. A sample time series forecast output from a statistical package.

budget, lagged sales, market share, economic indicators, and the like. The predictive distribution of the forecast can then be used as the probability distribution for the unknown quantity. Here, the emphasis is not on the point forecast generated by the model but rather the probabilistic information that is contained in the predictive distribution.

SOME CONSIDERATIONS

The use of data can be very useful in determining an appropriate probability distribution for an uncertain event. Historical data about the uncertainty can provide a glimpse of the past behavior of the uncertainties being studied, while related information may provide a good basis for making inferences about these uncertainties.

Despite the many advantages of using data, one must still be cautious of falling into the following traps that are common in this process:

1. *Framing Traps.* Frame blindness refers to the tendency of approaching a problem in an inappropriate manner because one has already accepted a specific framework with little thought leading to the discounting of better alternatives [8]. This narrowness in perspective often blinds decision makers. A common tendency is to lock in on a data set and discard any other theory or model that may reject this data set before doing a reasonable exploration of options. This can be due to a number of reasons such as having an initial cost associated with the data set, the data set being accepted as a common standard in the past, or perhaps its being attributable to a specific individual/source/group.
2. *Illusion of Objectivity.* One particular phenomenon with the use of data is the “illusion of objectivity” [9]. This refers to the distortion in the stakeholder’s understanding of the situation by making him or her believe that the assessments made using the data are purely objective and free from any

input from individuals. In many cases, the data used in the generation of probability assessments are devoid of human inputs but the choice of which data to use and how to model the data (including, for example, distributional assumptions or choice of a model in a regression setting) often involves a decision maker who ascertains why the use of such data over others is appropriate.

3. *Purity of Data.* Related to the notion of objectivity is the “purity of data” phenomenon, where decision makers often eliminate all sources of information that are attributable to individuals. In many instances however, information from individuals can be very useful and insightful. Research has shown that combining forecasts (see **Bayesian Aggregation of Experts’ Forecasts; Combining Forecasts.**) can lead to improvements in forecasting accuracy and this is true regardless of whether the forecasts come from individuals, groups, models or data.

Data can be a powerful tool in providing us more information about uncertainties that we have limited information on. They are useful as long as we keep in mind that data can never be used without a sprinkling of caution and a good dose of critical thought.

ASSESSING REMAINING USEFUL LIFETIME OF PRODUCTS

SAMI KARA

Life Cycle Engineering and Management
Research Group School of Mechanical &
Manufacturing Engineering, The
University of New South Wales, Sydney,
NSW, Australia

INTRODUCTION

The global society has experienced a growing awareness in the last couple of decade to develop a sustainable society. The two main drivers of this awareness has been the increased problem of resource scarcity and the environmental impact. Manufacturing industry has been the most affected from this due to the fact that they consume the largest amount of natural resources and by far the largest contributor to the environmental impact. As a result, manufacturing industries around the world have been investigating the possibilities of “doing more with less” in order to reduce the resource consumption and the associated environmental impact. A number of strategies have been recently developed to achieve this. One of these strategies is shifting manufacturing focus from selling product to selling service so that the manufacturing companies can keep the ownership of the product from cradle-to-grave [1], and therefore achieving multiple use of out selected components and subassemblies. For instance, companies such as Fuji-Xerox manage to achieve up to seven life-times out of same components. The other strategy is to establish a closed-loop manufacturing system [1]. The underlying idea is that the end-of-life (EOL) products are not waste, but are valuable resources. They are responsible in sustainability development is therefore expanded to include manufacturing firms for taking back their used products for EOL product recovery [2]. Both of these

strategies are mutually supportive of each other, since they both encourage extension of product life hence require EOL decision making at the end of their life-cycle.

Whether it is for selling use or EOL product recovery, EOL decision making consists of three important options such as reuse, recycle, and remanufacture [3]. Among these options, reuse of components is, in many cases, an environmentally effective and economically efficient EOL option [4]. The concept of component reuse stems from the fact that many components have a design life that exceeds the life expectancy of the product itself. For example, Mazhar *et al.* [5] provided empirical evidence that the physical life of an electric motor often exceeds the life expectancy of a washing machine. There are similar findings that have been reported for other products such as one-time-use cameras [6] and fuser roller of photocopiers [7]. Extending the useful life of these components can help minimize the waste and the resource consumption associated with making a whole new product.

While some companies deem reuse of components as a helpful tool for creating a close-loop economy, many of them see the implementation of the strategy as a challenge. One of the major obstacles is the lack of information on the remaining useful life of products. This information is crucial for determining their reuse potential which would justify the subsequent disassembly and reuse decision [8,9]. In addition, the remaining useful life has always been an important issue for maintenance management [2]. From the physical lifetime perspective, the remaining life of a system is defined in terms of physical condition, that is, how long an item will continue to perform its intended functions within a specified usage environment [10]. There have been many studies focused on the remaining physical life assessment such as by using accelerated life testing, predictive maintenance, and nondestructive testing [8]. However, the available methods are either relatively

complex, involving the time-consuming processes such as disassembly and testing of an individual component, or sometimes not applicable to the stationary components.

In addition, further studies reveal that the end of useful life of an item is also subject to the technology improvement [11–13]. As technology improves, there is a chance that underlying components may not be reused. The significance of change can be completely or partially dependent on whether the technology is improving at breakthrough or at incremental progress. However, regardless of the degree of change, technological progress has an impact on market demand of a product and its components. The faster and the greater the penetration of a new innovation, the sooner the old product technology becomes obsolete. Consequently, the remaining useful life of component is not only governed by its physical life, but by its technological life as well [11]. As a result, both these factors should be taken into consideration before an EOL decision is made.

ASSESSING REMAINING USEFUL LIFETIME

The following Fig. 1 shows an integrated model for estimating the remaining useful life of components.

As shown in Fig. 1, the first step in estimating the remaining useful life is the assessment of physical lifetime, T_P , which is the difference between the operating life, T_O , and the usage life, T_U , of the component. As mentioned earlier, the remaining useful life of components is governed not only by the physical, but also the technology life as well. Therefore, the second step in this process is the assessment of the technology life, T_T . Finally, the remaining useful life, T_R , can be estimated as the minimum of these values. The following section will explain these concepts in detail.

ASSESSMENT OF PHYSICAL LIFETIME

Estimation of Operating Life, T_O

The parameter, T_O , is governed by the failure datum, which is the time that a component is

Figure 1. Integrated methodology for the remaining useful lifetime estimation.

expected to experience a failure or disruption so that it cannot resume any of its normal operations. The failure rate of an item is the standard metric for reliability predictions, calculated as the average number of failures per unit of time [14]. For many electronic components, it is possible to consider their failure rate to be constant and characterized by the exponential distribution [15]. However, it is more common to find most of the component failures follow a typical failure rate curve. The “bathtub curve” is often mentioned in this context. However, other curves are more relevant in practice [15]. The failure rate can be characterized by the Weibull distribution [16].

The information on failure rate and the associated probability distribution can be used to derive the time-to-failure (the operating life expectancy) of a particular component [16]. The mean-time-to-failure (MTTF) is a widely used statistical description that specifies the average life or the most likely value to be expected in a group of data [16]. Nevertheless, it has been recommended that the MTTF is to be used in conjunction with the corresponding life parameters (e.g., Weibull parameters) in order to represent meaningful characteristics and uncertainty of a component’s lifetime [16].

As an alternative to the physical testing approach, the field failure data analysis has also been extensively used to assess the life characteristics of components [17,18]. The main advantage of this technique is that it accounts for all the actual field environments and the possible failure mechanisms. The calculated MTTF can be a closer value to the true life expectancy of the component population. Moreover, most companies already have access to the information since it is usually an integral part of their quality control program. There is no new investment required.

The collected data can be analyzed using the Weibull method to determine the life characteristic parameters including the MTTF of the component. Its most common form is the two-parameter Weibull distribution [16]:

$$F(t) = 1 - \exp \left[- \left(\frac{t}{\eta} \right)^\beta \right], \quad (1)$$

where $F(t)$ represents the fraction of units failing and “ t ” is the time-to-failure. The two parameters that characterize the life distribution are the scale parameter, η , which measures the time at which 63.2% population will fail, and the shape parameter, β , which identifies the mode of failure. A value of $\beta < 1$ indicates infant mortality, $\beta = 1$ means a random failure, and $\beta > 1$ describes a wear-out failure. The corresponding MTTF, of the two-parameter Weibull function can be expressed in terms of its scale parameter, η , and the gamma function, Γ , of the shape parameter, β as [16]:

$$\text{MTTF} = \eta \times \Gamma \left[\frac{(\beta + 1)}{\beta} \right]. \quad (2)$$

The most common method used for estimating parameters in Weibull analysis are median rank regression (MRR) and maximum likelihood estimation (MLE). The results provide the estimated values of life distribution parameters η and β , and the corresponding MTTF of the component, hence T_O for a given component [17,18].

Estimation of Usage Life, T_U

The usage life of a product, T_U , is the second element to be considered in estimating the remaining physical lifetime of a component. It is a critical parameter that indicates the actual age measured in operating times (hours, cycles, kilometers, and so on) that a component has been used. One way to determine the age is by measuring in calendar time units (i.e., days, weeks, months, and years) and/or assume a constant usage intensity throughout its lifespan [12,19]. However, this would not produce a realistic estimate, therefore, a number of methodologies have been developed to carry out a more realistic assessment of this critical parameter. Majority of these methodologies utilize life-cycle data collected from various sources. The information on the variation in usage intensity overtime of a product can be collected through a number of ways, for example, using data recording unit in consumer products; such as electronic data log (EDL) [20], life-cycle data acquisition unit—the whitebox [21], life-cycle unit [22], and watchdog [23], or using field surveys.

Statistical Techniques. The basic idea behind this technique is that the usage conditions and level of intensity that may change and can depend on the obsolescence of a product with respect to time. As a product ages, its usage-intensity is expected to be less. For example, the frequency and duration with which a 10-year-old television is used may be less than a 2-year-old television in a household. This may be due to the attractiveness of the new design as well as the superior features and performance of the new television that has over the 10-year-old with malfunctions and inefficient energy consumption.

The main aim is to compile locally designed basic statistics on product usage intensity. The results can then be used to estimate the usage history and its changing pattern in relation to the age of a product. In order to do this, the collected data can be statistically analyzed to derive the following statistical information:

1. the probability function that describes the probability of usage intensity during a particular age of product usage (in year);
2. the average usage intensity during a particular age of product usage, called $\bar{X}_i$ where “ i ” is the order of year 1 to n .

For instance, if it is assumed that a product is likely to spend $\bar{X}_1$ h per day in active

mode during the first year, $\bar{X}_2$ h per day during the second year, $\bar{X}_3$ h per day during the third year, and so forth until $\bar{X}_n$ during the n th year of its service life. The average total hours that a product has been used over n years period, that is, usage-intensity age, T_U , can be calculated as:

$$T_U = \sum_{i=1}^n \bar{X}_i \times 365. \quad (3)$$

Note that the T_U of the components is simply equal to the T_U of the product itself [24,25].

Regression Analysis. In order to use this technique, a data trend analysis needs to be carried out. In the case of a strong trend of data, regression analysis is a useful technique, particularly because of its ability to provide an answer on how each of the explanatory variables contributes toward the estimation of the response variable. The following Fig. 2 shows life-cycle data collected from an electric motor of a washing machine during its lifetime. They show a strong data trend in between the age of the electric motor, speed, and temperature, therefore the regression analysis is particularly suitable in this case.

In its generic form,

$$Y = a + b_1X_1 + b_2X_2 + \dots + b_kX_k, \quad (4)$$

Figure 2. Life-cycle data for an electric motor [26,27].

where Y is the response variable, a and b are regression coefficients, $X_1, X_2, \dots, X_k$ represent the explanatory variables and k is the total number of explanatory variables. There are different types of regression analysis, such as simple and multiple regressions. Simple regression involves two variables, the dependent variable and one independent variable. Multiple regression involves many variables, one dependent variables and many independent variables. The Equation (4) is valid for simple and multiple regressions, whereas the quadratic and higher degree regression equations need to be solved by nonlinear regression analysis.

The purpose of carrying out regression analysis is to know the explanatory variables, also called *predictors* or *independent variables*, such as motor speed and temperature, are related to the response (dependent) variable which is the age of the product, an electric motor, in this case. The primary goal is to estimate or predict machine's life given the current and past values of the explanatory variables. The results of an analysis for the electric motor are shown in Table 1. The effect of each explanatory parameter on the overall result, based on the individual R^2 values, is shown in Table 2.

Table 1. Results of Linear Multiple Regression Analysis [28]

Response Variable	T_U (years)
Explanatory variables	ω, T, P, I, V
Regression equation	$T_U = 10 \times I + 0.81 \times \omega + 0.0606 \times P + 0.0095 \times T - 0.111 \times V - 1152.9$
R^2	0.8232

Table 2. Explanatory Variables Contribution to R^2 [28]

Speed (ω)	Power (P)	Temperature (T)	Voltage (V)	Current (I)
0.8005	0.0221	0.0000	0.0006	0.0000

It can be seen that motor rotation speed (ω) and power (P) are the dominating parameters in the final result. This fact has been confirmed by a very clear rising trend in the monitored values of speed, and power measurements are found reasonably related to the age of the motor during the initial years of operation. No or negligible contributions by voltage (V), current (I), and winding temperature (T) have been found due to a flat response from these parameters over the entire life of the electric motor. These techniques are proved to be inadequate when there is no, reverse, or fluctuating trend in the observed data.

Kriging Techniques. Kriging techniques are modified forms of multiple linear regression. They are often associated with the acronym BLUE Best Linear Unbiased Estimator [27]. Ordinary kriging, also called *punctual kriging*, is the simplest and most common form of kriging. It is suitable for data that shows weak trends. Universal kriging is similar to ordinary kriging but used when a strong trend is present in the data samples. Cokriging is a multivariable extension of kriging. It is capable of estimating one variable from several variables by utilizing the concept of estimating primary and secondary variables at the same time.

Kriging utilizes the information from a variogram to find an optimal set of weight that are used in estimating an unknown value at know condition. A variogram as shown in Fig. 3, summarizes the relationship between differences in pairs of measurement and the distance of the corresponding points from each other.

Sill and Range are defined at the region where the variance levels off (the Sill) after a certain distance (the Range) beyond which observations appear independent, that is, where the variance no longer increases. Nugget is defined when the variogram appears not to go through the origin. There are several different models of variograms including linear, exponential, and spherical and the Gaussian models. The spherical model is widely used and considered as an ideal model since it accounts for all three parameters such as Sill, Range, and Nugget.

Figure 3. Variogram with Nugget, Sill, and Range [27].

The variogram is computed by measuring the mean-squared difference of a value of interest evaluated at two points, for example, x and $x + h$. This mean-squared difference is the semivariance, v , and is assigned to the value h , which is known as the lag. A plot of the semivariance, v , versus h is the variogram.

Mathematically,

$$v = \begin{cases} C + C \left[1.5 \left(\frac{h}{a} \right) - 0.5 \left(\frac{h}{a} \right)^3 \right], & h < a, \\ C_0 + C, & h > a, \end{cases} \quad (5)$$

where C_0 = Nugget, $C + C_0$ = Sill, a = Range, h = Distance, and v = Semivariance.

When a variogram is used to describe the correlation of different variables it is called *cross-variogram*, which is used in cokriging.

Table 3 below shows the summary of the results of the different kriging techniques for the previous electric motor case.

There are only small differences between the values estimated by universal kriging and Cokriging, in this case. Kriging procedures have a major problem of having singular matrices when there are a lot of data sets with the same data value. This scenario results in a large number of zero entries in the distance

matrix that makes the determinant of the matrix equal to zero. In other words, kriging procedures are more suitable for data sets with distinct data points.

Vibration Analysis. Vibration analysis can extend the knowledge of the machine condition and thus improve the remaining useful life estimate. The vibration analysis is also useful since the suddenly occurring impulse reveals an obvious degradation in a product's performance. Hence the goal of the vibration analysis is to process each vibration signal and extract a set of suitable trending indicators. Later, these trending indicators can be fitted to a suitable model by using one of the techniques mentioned above in order to predict the useful remaining life of products. Although trending can be done by using three indicators, namely, comparing the constant percentage bandwidth (CPB), cepstrum, and envelope analyses, two of those, CPB and cepstrum analysis will be discussed here. Further readings can be found at Refs 29 and 30.

CPB spectra is a robust and versatile fault detection method. Measurement of CPB spectra has been developed even before the fast fourier transformation (FFT) algorithm

Table 3. Results of Kriging Techniques [28]

Response variable	Ordinary Kriging		Universal Kriging	Cokriging
	Years			
Explanatory variables	ω, T	T, P	ω, T	ω, T, P, I, V
R ²	0.80	0.30	0.8592	0.8592

was implemented in vibration analyzers with octave-band filters [29,31]. In order to obtain degradation trend for a given component, a reference spectrum $R[f]$ is generated from the first four CPB spectra by finding a maximum magnitude in each band. The reference spectrum represents the initial state of a product without mechanical faults. Then, a mask $M[f]$ is created by a lateral shift (“widening”) of the reference spectrum $R[f]$ in order to compensate for large speed changes (greater than the percentage bandwidth). The widening is achieved by taking a maximum value of three adjacent frequency components for each center frequency. The mask is then compared with subsequent spectra, and any protrusions above the mask are recorded for trending the fault development. Amplitudes in dB are compared since equal changes in severity are represented by equal changes on a log amplitude scale [29,31]. A significant change corresponds to an increase by 6 dB (ratio of 2:1), while a serious change corresponds to 20 dB (ratio 10:1). This procedure proved to be more reliable than absolute criteria for vibration severity [29,31]. After this, a sequence of difference spectra is computed as

$$Dn[f] = Xn[f] - M[f], \quad n = 5, 6, \dots, N, \quad (6)$$

where $Dn[f]$ is the n th difference spectrum in dB, $Xn[f]$ is the n th CPB spectrum, $M[f]$ is the mask of $R[f]$ and N is the total number of CPB spectra. Only positive differences are of practical interest, thus all negative differences are replaced by 0 dB.

Figure 4a illustrates the slice at 10,293 Hz with an exponential trend exceeding the threshold of 10 dB at day 501, end-of-life of an electric motor T_{EOL} , during a condition monitoring experiment of an electric motor. To attempt prognosis, the trend was computed only from the data up to day 490. The subsequent rapid decline is a consequence of a step change characterized by much lower vibration level at many frequencies. Figure 4b shows the CPB differences at the adjacent center frequency of 9715 Hz. The data exhibit a similar exponential trend reaching the value of 9.3 dB, hence very close to the 10-dB limit. In addition, both trends

exceeded the threshold of 6 dB (indicator of a significant change) almost simultaneously, near the day 425. This suggests that it is the overall trend that quantifies the machine condition, rather than the individual data points, which fluctuate significantly. Therefore, analyzing the CPB differences in a significant band (around 10 kHz in this case) has provided a fault prognosis. Although different curve fitting techniques can be used, two curve fitting methods are shown in Fig. 4 for extracting the trend of each indicator. First, a straight line is fitted by finding a first-order polynomial in the least squares sense. Secondly, an exponential curve $y = Ae^{t+B}$ is fitted by optimizing its parameters using the simplex direct search method. Finally, the method yielding a lower sum of squares error (SSE) can be selected for plotting the trend.

Finally, a CDS is calculated as:

$$CDS(n) = 10 \log_{10} \left[\sum_{f=0}^{f_{\max}} 10^{Dn[f]/10} \right], \quad n = 5, 6, \dots, N, \quad (7)$$

where $CDS[n]$ is the dB increase of the n th spectrum $Xn[f]$ above the mask $M[f]$. The CDS is computed by converting each $Dn[f]$ from dB to the amplitude squared scale, then summing the squared ratio values (integrating over all frequencies) and finally converting the resulting scalar to dB. For this reason, the CDS is a measure of the overall spectrum change, since it quantifies the total increase at all frequencies. This is because the effect of the transfer function is removed, thus allowing to monitor significant changes regardless of the frequency of occurrence. Since the outcome is linear (Fig. 4c), the interpretation is much easier than the others.

The cepstrum analysis can also be used in fault diagnostics for its ability to enhance periodic spectrum structures (harmonics, sidebands) in the same way as spectrum highlights periodicity in time signals [31]. It has been applied to diagnostics of gears [43], bearings, and turbomachinery [31]. The cepstrum is defined as the inverse Fourier transform of a logarithmic spectrum. It is a nonlinear method due to the use

Figure 4. CPB-based trending of electric motors: (a) CPB differences at the center frequency 10,293 Hz, (b) CPB differences at center frequency 9715 Hz, (c) CPB difference sum (CDS) [29,30].

of the logarithm (which determines many cepstrum properties). Two main types of cepstra are commonly used. The real cepstrum is obtained by the inverse DFT of the logarithmic amplitude spectrum, hence it contains no phase information and is used only for analysis. The complex cepstrum is computed by the inverse DFT of the complex logarithmic spectrum. The phase information is retained, thus the complex cepstrum is invertible and allows reconstruction of the time-domain signal.

The following Fig. 5 shows a degradation trend developed for an electric motor by using the cepstrum analysis at 10 ms frequency component. The time axis starts on day 340 in order to show the end-of-life the product. The data exhibits an almost constant trend, while a dramatic increase of 20 dB occurs at T_{EOL} , which indicates the end-of-life the electric motor.

At this point, any previously mentioned linear regression techniques can be used to develop a regression model to predict the

Figure 5. Trending of the real cepstrum at frequency of 10 ms for the electric motor [29,30].

remaining useful life of a component under a given usage condition.

In this section, two possible vibration indicators are used for estimating the remaining useful life of components. However, vibration parameters can fluctuate to some extent, possibly due to load changes caused by the usage condition of the electric motor. Despite this fluctuation, the proposed indicators can be useful for estimating the remaining life components. When the data exhibit a strong trend, the remaining life components can be estimated by fitting a straight line (or exponential curve) and extrapolating the trend to the thresholds of 6 or 10 dB. A more advanced alternative would be to use multiple linear regressions of several vibration parameters. However, as mentioned earlier, these techniques tend to struggle when the trend is weak or fluctuating hence a more accurate model is necessary. The next section will discuss one of these models based on neural networks because of their ability to deal with complex trends and to capture nonlinear input–output relationships.

Artificial Neural Networks. The traditional techniques have been found struggling in certain areas if there are parametric trend fluctuations and a high number of inputs. Research indicates that a neural network is a powerful data-modeling tool that is able to manipulate complex input/output relationships in order to cope with the shortcomings of the previous techniques.

The following Fig. 6 shows an example of neural network model to estimate the remaining useful life of a product by detecting the complex input structures in time series, which is presented to the model network. The features, input, and output of the proposed neural network model are as follows:

- One input layer of 5 neurons—one for each measured variable.
- One hidden layer of 8 neurons.
- One output layer of 1 output neuron.
- Input variables: rpm, temperature, power, current, and voltage.

Figure 6. The structure of the neural network model [26].

Figure 7. Neural network performance after training [26].

The model's output was obtained and compared to the experimentally measured values by using the postreg function. This function basically performs linear regression between targets (experimentally measured values) and the network response to the presented inputs (condition monitoring data). The model's response to all the three sets of life-cycle data was remarkably accurate especially for the seen and entire data sets as shown in Fig. 7.

Although the R^2 value is still relatively low, once trained, the neural network model yields outputs very closely related to the desired outputs.

Estimation of Remaining Physical Life

As shown in Fig. 1, the estimation of physical lifetime (T_P) requires two variables, namely, operating life T_O , and usage life T_U . The first element, T_O , is an estimated operating life expectancy, which is governed by the failure datum or the expected time-to-failure. The section titled "Estimation of Operating Life, T_O " above explains how this parameter can be obtained. The second element, T_U , is the usage life that represents the true age or used

life of components. The section titled "Estimation of Usage Life, T_U " above explains how these parameters can be estimated by using various methodologies. When the values of the two parameters are obtained, the remaining physical life, T_P , of a component is then calculated as a difference between T_O and T_U . This can be described mathematically as

$$T_P = T_O - T_U. \quad (8)$$

REMAINING TECHNOLOGY LIFETIME ESTIMATE

As mentioned before, the remaining useful life of components is not only governed by its physical life, but by its technological life as well. In order to have a realistic estimate, the technology life of a product must be taken into account, which requires the forecasting of the technology of a given product. Growth curves are commonly used in forecasting the adoption of new technology and hence the obsolescence of its predecessors [32]. This is because the life of a particular product's technology is not random, rather, it forms an

Figure 8. Hypothetical example of product technology substitution [24,25].

S-shaped curve. This enables a mathematical model to be used for forecasting [33].

Market demand is often observed as a related parameter that both captures and drives the technology innovations [34]. The market fraction, f , of a product technology generally increases with time along the S-shaped curve. Similarly, the decay in the fraction represented by the old product generation described a reversed S-curve, as shown in Fig. 8. Therefore, when the historical data is available, a partly established curve can be fitted to the data from its emergence (or the earliest data point) to the present day. It can be assumed that it will continue to grow along an S-curve, and as a result the historical trend will therefore be extrapolated into the future.

There are a number of S-shaped curves which are examined in the forecasting literature and can be used including the Fisher–Pry model [34], Blackman model [35], Floyd model [36], Gompertz curve [37], and the Weibull distribution function [38]. Note that both the most popular models, Fisher–Pry model and Blackman model, are actually different forms of Pearl curves or the standard logistic function (SLF) [39]. However, there is still some debate as to the accuracy and the superiority among all the models. It was observed that, in general, the difference in accuracy and disparity of these models are not greatly significant. It also varies from case to case [40,41]. Therefore,

the simple and the widely used SLF can be used to forecast the technological lifetime of products and their components for the estimation of technology life.

The SLF follows the logistic law of growth that assumes an exponential growth until an upper inherent limit, L , in the system is approached, as shown in Fig. 9.

Mathematically, an SLF can be defined as [39]:

$$p = \frac{L}{1 + ae^{-bt}}, \quad (9)$$

where p is the value of the measuring parameter, which is thus replaced by market fraction, f ; t is the time unit in years; L is the

Figure 9. Standard logistic curve (S-shaped curve).

natural limit; a is a constant scale parameter; and b is a shape parameter. Note that the value of a yields p when t is zero and b adjusts how quickly the response changes with changing t as a single unit.

So far, the technology forecast is referred to in terms of market share. How does this predict the remaining technology life? As the expected result indicates the future market share of technologies, a manufacturer needs to identify the market share datum that defines the technological life limit, T_L . This value depends on a manufacturer's individual perspective on the balance between supply and demand of components [42]. For example, a manufacturing company decides that the product under investigation will be obsolete when the demand drops to, say, 20%. A manufacturer makes this individual decision based upon relevant facts and information, including the economical capability.

As a general rule, the remaining technological life, T_t , of a technology and its components is estimated as the outstanding period from present, T_{now} , to the point in time where the demand is predicted to reach the given market share datum, T_L as shown in Fig. 10.

This relationship can be shown mathematically as:

$$T_t = T_L - T_{\text{now}}.$$

Note that the T_t of the components that belong to the old technology is the same as the T_t of the old technology itself. However, the components which appear to remain

applicable in the new technology have their remaining life extended accordingly.

INTEGRATED MODEL FOR THE REMAINING USEFUL LIFETIME ESTIMATION

The concept behind the integrated assessment is that when considering components for reuse, the components should have adequate remaining life in terms of both physical and technological aspects. The integrated model shown in Fig. 1 aims to achieve this. For this reason, the resulting T_R is governed by the shorter value of the two parameters. For instance, if T_P is less than T_t , then T_R cannot be greater and will be equal to the value of T_P itself and vice versa. This relationship can be mathematically written as

$$T_R = \min(T_P, T_t). \quad (10)$$

Furthermore, in order to determine the reuse potential of used components, their remaining life, T_R , should also be at least greater than the average expected service life of a product, T_{AV} , that is, $T_R \geq T_{AV}$.

CONCLUSIONS

An accurate prediction of the remaining useful life has become increasingly important in order to make an appropriate EOL decision for products or components. This is

Figure 10. An estimation for the remaining technology life, T_t [24,25].

mainly due to the worldwide drivers such as the increased problem of resource scarcity and the environmental impact. However, the remaining useful life assessment is a complex process due to the uncertainties associated with the condition of the returned product. Therefore an accurate prediction must take into account not only the remaining physical, but also the technology life as well.

In order to achieve this, this article presents an integrated model to estimate the remaining useful life of components. The model integrates the physical life time and the technology life estimation by using various methodologies. This study provides a very comprehensive foundation for further research and decision making on value recovery through reuse. More research into the development of prognostic tools is required in order to develop more reliable EOL decision making tools.

ASSOCIATION OF EUROPEAN OPERATIONAL RESEARCH SOCIETIES

M. GRAZIA SPERANZA
Department of Economics
and Management,
University of Brescia,
C.da S.Chiera 50,
25122 Brescia, Italy

THE FOUNDATION OF EURO

At the International Federation of Operational Research Societies (IFORS) conference in Dublin in 1972, the participating presidents of European Operational Research (OR) societies met and agreed that more could be done to improve communication and cooperation on a European level. Representatives of 11 European countries held a meeting in Düsseldorf on 3 and 4 September, 1973, where it was agreed that European national societies would be contacted for their views on various potential initiatives, including setting up a European coordinating body [1]. With strong support from national societies, a further meeting was held in Amsterdam in May 1974 where it was agreed to “formalize and institutionalize increased European cooperation” [2]. In addition, it was also agreed to organize the First European Conference for OR in January 1975 in Brussels [1]. Despite the short timescale, the conference attracted around 500 participants and feedback suggested that the atmosphere was constructive. “At the very festive and impressive Final Session the draft of the agreement was signed by the Representatives of ten European OR Societies (Belgium, Denmark, Finland, Germany, Great Britain, Greece, Ireland, Netherlands, Sweden, Switzerland)” [1]. This was the foundation of the Association of European Operational Research Societies (EURO) within IFORS. In addition, after the Final Session, the Provisional Council of EURO met and agreed to form a Constitutional Committee [1].

As a regional grouping of IFORS, the aim of EURO is to provide effective opportunities for members of national societies to collaborate and further the theory and practice of OR. In addition to the Association itself, appropriate instruments have also been developed to achieve this aim. This paper gives examples of successful activities that reinforce the validity of such a grouping.

THE HISTORY OF EURO

“On 8 March 1976, the Honorary Secretary [Roger Eddison] announced: ‘I hereby declare that EURO, The Association of European Operational Research Societies within IFORS, is now formally constituted with effect from 5 March 1976 and the draft statutes circulated on 29 June 1975 are effective’” [2].

By 18 June, 1976, “the definitive statutes and by-laws of EURO were ratified in total by the OR societies of: Belgium, Denmark, Finland, France, Germany, Greece, Ireland, Italy, The Netherlands, Spain, Switzerland and the United Kingdom” [3]. The Association comprises a Council of national society representatives, an Executive Committee of EURO officers, and a number of EURO support staff to run the office and provide other

liaison roles. At the first official meeting of the Council of EURO, held on 18 June, 1976 in Brussels, elections took place for the officers of the association. The outcome was

President: Professor Dr. H.-J. Zimmermann

Vice-President: Professor Dr. G. Kreweras

Secretary: Professor Dr. R. Eddison

Treasurer: Professor Dr. J.P. Brans

“It was unanimously agreed that these four would form the executive committee” [3]. Professor Zimmermann remained the EURO President for four years, but it was agreed that subsequent Presidents would retain the post for two years.

The membership of EURO increased as more national societies joined IFORS and consideration was given to countries outside of the European Union. For instance, in November 1987, the Executive Committee received a letter from the President of the Operations Research Society of South Africa requesting membership of EURO. There is no African regional grouping of IFORS and the case was made that collaborative links already existed with some individuals in EURO and there was better access in terms of transport to European countries.

As the Association and its membership grew, it was becoming increasingly important to formalize the administrative arrangements. Although the proposal for a permanent secretariat was discussed on numerous occasions, EURO was not in a financial position to set up an office until 1993 [4]. The EURO office was set up in Brussels and incorporates a number of administrative tasks

that support the function of the Executive Committee.

THE ORGANIZATION OF EURO

EURO (www.euro-online.org) is an association of national OR societies. The members of EURO at present are the national societies of the 30 countries listed in Table 1. The organization of EURO is based on the Executive Committee, the Council, and the staff. The Executive Committee (EC) is composed of seven officers: the President, the President-Elect or the Past-President, the Vice-President responsible for conferences (VP1), the Vice-President responsible for education (VP2), the Vice-President responsible for publications (VP3), a secretary responsible for the organization of meetings and for the minutes, and a treasurer. The term of office of the President and the Vice-Presidents is two years. Their appointment cannot be renewed. Each President is member of the EC one year before the term as President-Elect and one year after as Past-President. The secretary and the treasurer appointment can be renewed. They are confirmed by the Council every two years. The Council is composed of two representatives from each of the member societies and meets once a year, during the EURO or the IFORS conferences. Through the Council, the strategy and the actions of the EC are coordinated with the activities of the member societies. EURO is one of the regional groupings of IFORS, and the IFORS Vice-President (EURO) is invited to the meetings of the EC. The staff includes a manager and a webmaster.

Table 1. List of EURO Members

Austria	Germany	Portugal
Belarus	Hungary	Serbia
Belgium	Iceland	Slovakia
Bulgaria	Ireland	Slovenia
Croatia	Israel	South Africa
Czech Republic	Italy	Spain
Denmark	Lithuania	Sweden
Finland	Netherlands	Switzerland
France	Norway	Turkey
Greece	Poland	United Kingdom

Table 2. List of EURO Presidents

Duration	Name	Country	Duration	Name	Country
1975–1978	Hans-Jürgen Zimmermann	Germany	1995–1996	Paolo Toth	Italy
1979–1980	Birger Rapp	Sweden	1997–1998	Jan Weglarz	Poland
1981–1982	Rolfe Tomlinson	UK	1999–2000	Christoph Schneeweiß	Germany
1983–1984	Jean-Pierre Brans	Belgium	2001–2002	Philippe Vincke	Belgium
1985–1986	Bernard Roy	France	2003–2004	Laureano Escudero	Spain
1987–1988	Dominique de Werra	Switzerland	2005–2006	Alexis Tsoukiàs	France
1989–1990	Jakob Krarup	Denmark	2007–2008	Martine Labbé	Belgium
1991–1992	Jaap Spronk	Netherlands	2009–2010	Valerie Belton	UK
1993–1994	Maurice Shutler	UK	2011–2012	M. Grazia Speranza	Italy

Up to 2012, there have been 18 presidents of 11 nationalities (Table 2), demonstrating a truly international strength in both the discipline and motivation to coordinate across a European community. The President-Elect for 2012 is Gerhard Wäscher from Germany.

CONFERENCES

IFORS conferences have always been triennial events. “During the 6th IFORS Conference in 1972 there was a widespread recognition that, with the venues of the next two IFORS conferences determined, there would not be another international conference in Europe for nine years” [2]. At the meeting held in Amsterdam in May 1974, in addition to agreeing to formalize EURO as a regional grouping of IFORS, the representatives of the European OR societies agreed to “assemble operational researchers from all Western European countries for the First European Conference on Operational Research” [2]. As already mentioned, the first European Conference on Operational Research (EURO I) was held in Brussels in January 1975 and attracted around 500 participants. A number of national societies, as well as IFORS, offered financial support [2]. Following the success of EURO I, a second conference was arranged to be held in Stockholm in April 1976. In 1977, EURO co-sponsored the TIMS (Institute of Management Science) XIII international meeting, which was held in Athens. As EURO did not take a leading part in its organization, it is not recorded as part of the EURO-k conference series, but at the Executive Committee meeting held in May 1978,

it was agreed to participate in a second joint conference with TIMS in 1982 in Lausanne which would also be recorded as the fifth EURO conference. The IFORS triennial conference was held in 1978, and the next EURO conference was held in 1979, and thereafter, EURO conferences have been arranged for the interim two years between IFORS conferences. Table 3 lists the EURO-k conferences held to date.

In the early years, EURO-k conferences attracted 500–600 participants. In 1982, Tilanus [5] looked in detail at the composition of the EURO-k conferences to date and considered factors such as national society membership and equivalent American conferences. He also considered many issues and his opinion was that EURO-k conferences “should, and may, in fact, become larger” [5]. From 1991, EURO-k conferences exceeded 600 participants. Despite some fear that conference participation would reduce with advent of the Internet, participation in fact increased further. In 2007, conference participation exceeded 2000, and this is now the figure typically planned for and achieved. As one of the initial instruments proposed by EURO, the growth in participation demonstrates the benefits the European regional grouping can bring.

WORKING GROUPS

The idea of developing working groups to focus on specific topics within OR was first discussed at the meeting held in Amsterdam in May 1974. Eight working groups were established at the first EURO conference in

Table 3. List of EURO-k Conferences

Year	City	Year	City	Year	City
1975	Brussels	1989	Belgrade	2003	Istanbul
1976	Stockholm	1991	Aachen	2004	Rhodes
1979	Amsterdam	1992	Helsinki (joint with TIMS)	2006	Reykjavik
1980	Cambridge	1994	Glasgow	2007	Prague
1982	Lausanne (joint with TIMS)	1995	Jerusalem	2009	Bonn

Brussels in January 1975: OR and Energy Problems; OR Applied to Health Services; Fuzzy Sets; OR in Government and the Public Sector; Multicriteria Decisions; OR in Banking; OR in Regional and Urban Planning; and Education. “In the early years of EURO Germain Kreweras and Jakob Krarup edited a charter providing a structure to the Working Groups within a EURO framework.” [6]. Krarup [7] provided an overview of the EURO working groups in 1984, at which point six working groups were highly active, including four of those established in 1975. There are currently 28 working groups within EURO.

The working group framework encourages collaborative work to be carried out in both established and newer topics in OR. This long-standing instrument is dynamic, is fluid, and can respond to emerging themes. In this case, the benefits of European collaboration on more specialized topics can lead to solutions to new problems.

PUBLICATIONS

The idea of starting a European journal was raised in the first meeting in Amsterdam in 1974 and received “considerable support” [8]. In January 1975, a committee was formed to investigate the feasibility of launching a journal dedicated to OR across Europe. Later that year, it was agreed that the *European Journal of Operational Research (EJOR)* be

established, and the first volume was published in 1977, in time for the second EURO conference. The first volume consisted of six issues published bimonthly with a total of 41 papers, and by 1981, there were three volumes containing 120 papers [9]. EJOR also originally included the *EURO Bulletin* which provided an update of European OR activity. “EJOR became a EURO journal in 1990 and since then has continuously grown in terms of reputation and quality (through measures such as the impact factor) to be one of leading journals of the international OR community” [10]. In 2010, EURO agreed to investigate the option of diversifying its portfolio of journals, and in 2011, three new journals were officially launched: *EURO Journal on Transportation and Logistics*; *EURO Journal on Computational Optimization*; and *EURO Journal on Decision Processes* [10]. These journals are an exciting new instrument, and they will complement EJOR as a means of further enhancing specialized areas of OR.

ADDITIONAL EURO INSTRUMENTS

In 1983, three additional instruments were proposed and “enthusiastically approved by our EURO council” [6]. The EURO Gold Medal was awarded for the first time to Hans-Jürgen Zimmermann at EURO VII in 1985. The award is “not only significant for the laureate but is also very important for

the promotion of OR in the public field by making leading persons and their contributions better known" [11]. The award is made at a EURO-k conference and the laureate is invited to give the opening lecture. Mini conferences were initiated in 1984 to offer a more focused event for specialized themes and with more limited participation. These conferences are "a democratic instrument giving opportunities to all the members of EURO, while a large EURO-k conference can only be organized by a selected country and ... only twice every three years" [6]. The first EURO Summer Institute, on Location Theory, was hugely successful and led onto further collaboration after the event [11]. The Summer Institutes, and subsequently Winter Institutes, are aimed at early stage researchers and places are limited so that the experience is unique and rewarding. The EURO General Support Fund was set up in 1994 as a way of encouraging and funding other appropriate activities. In 2001, ORP³ was introduced as "a forum promoting scientific and social exchanges between the members of the future generation of Operational Research in academic research" [12]. EURO now offers a number of further awards, the latest of which was approved for in July 2011 and will be presented annually to the authors of the best EJOR papers. Further attention to the future generations of researchers in OR is given with recent initiatives on education, from high school to postgraduate. The expansion of the EURO instruments is another indicator of a successful association and a recognition that EURO can also adapt over time.

CONCLUSIONS

The aim of EURO is to offer effective opportunities for members of national societies to collaborate and further the theory and practice of OR. EURO started "with very little money, the tools of EURO-k conferences, European Working Groups, a EURO Bulletin, a party working on a European OR journal and lots of enthusiasm" [1]. As EURO approaches its twenty-fifth conference, it can demonstrate a quantifiable increased its membership, conference participation, and instruments. It has

also been able to embrace new technologies to strengthen its communication capabilities across Europe. This time period has not been without its challenges and there may be many to come, but it is clear that the initial vision was achievable. With the continued commitment and enthusiasm of individual members, national society members, but above all a dedicated Executive Committee and support team over the years, EURO continues to thrive and will do for many years to come.

Acknowledgments

I wish to warmly acknowledge the support of Sarah Fores, EURO manager since October 2011, in exploring the EURO archives, analyzing the documents, deriving the relevant information, and drafting this paper.

ASYMPTOTIC BEHAVIOR OF CONTINUOUS-TIME MARKOV CHAINS

EYLEM TEKIN

Department of Industrial and
Systems Engineering, Texas
A&M University, College
Station, Texas

INTRODUCTION

Continuous-Time Markov chains (CTMCs) have a wide variety of applications in the real world, which span telecommunication, computer, queueing, manufacturing and distribution systems, and population growth models among others. In particular, Poisson process and birth and death processes are the classical examples of CTMCs that have been widely studied.

Consider a stochastic process that can be in various states over time. Let $X(t)$ denote the state of the system at time $t \geq 0$. $X(t)$, $t \geq 0$, is a random variable that takes values in a discrete set S , which is called the *state space*. The process $\{X(t), t \geq 0\}$ is a CTMC if

$$P\{X(t+s) = j | X(s) = i, X(u) = x(u), 0 \leq u < s\} \\ = P\{X(t+s) = j | X(s) = i\},$$

for all $s, t \geq 0$ and $i, j \in S$. In other words, the stochastic process $\{X(t), t \geq 0\}$ has the Markovian property such that the conditional distribution of the future state $X(t+s)$, given the current state $X(s)$ and the past states $X(u)$, $0 \leq u < s$, depends only on the current state and is independent of the past. A CTMC $\{X(t), t \geq 0\}$ with state space S is called *homogenous* or *stationary* if $P\{X(t+s) = j | X(s) = i\} = P\{X(t) = j | X(0) = i\}$ for all $t \geq 0$.

CTMC models are useful in describing the future statistical properties of systems. In particular, the asymptotic behavior of CTMCs has been important in many

applications. Several performance measures of practical interest can be computed by using the limiting distribution of $X(t)$ as $t \rightarrow \infty$. For example, for queueing systems, these performance measures may include the expected waiting time in queue, the expected number waiting in queue, and server utilization. In inventory systems, the performance measures of interest can be the expected inventory holding cost or expected number of lost sales.

While studying the asymptotic behavior of a CTMC, the imminent questions that arise are as follows: (i) Does the distribution of $X(t)$ approach a limit as $t \rightarrow \infty$? (ii) If the limiting distribution exists, is it unique? (iii) If there is a unique limiting distribution, how do we compute it? This article addresses these questions.

PRELIMINARIES

Consider a homogenous CTMC $\{X(t), t \geq 0\}$ on state space S with transition probability matrix $P(t) = [p_{ij}(t)]$ where

$$p_{ij}(t) = P\{X(t) = j | X(0) = i\} \text{ for } i, j \in S \\ \text{and } t \geq 0.$$

We are interested in studying the behavior of $P(t)$ as $t \rightarrow \infty$. However, the matrix $P(t)$ is hard to specify even for simple CTMCs. Therefore, we will use an alternative approach to investigate the behavior of $P(t)$ as $t \rightarrow \infty$.

We first present an equivalent definition of a CTMC as follows: Suppose that each time a stochastic process enters state i , the amount of time it spends in state i before making a transition to a different state is exponentially distributed with rate v_i , and when it leaves state i , it next enters state j , $i \neq j$, with probability p_{ij} . The time spent (i.e., sojourn time) in state i and the new state depends only on state i and not on the history of the system prior to time t because of

the memoryless property of the exponential distribution. Such a stochastic process is said to be a CTMC. Let $q_{ij} = v_i p_{ij}$ denote the rate of moving (i.e., transition rate) from state i to state j for $i, j \in S$ and $i \neq j$. Let us also define

$$q_{ii} = -\sum_{i \neq j} q_{ij} = -v_i,$$

for $i \in S$. Then, we can write the rate matrix $Q = [q_{ij}]$. This matrix is also called the (*infinitesimal*) *generator* of a CTMC. One important property of the rate matrix is that its rows sum to zero.

As an example, consider a machine that can be either up or down. The machine stays up for a random amount of time that is exponentially distributed with rate μ and it takes an exponentially distributed time with rate λ to fix it. Once it is fixed, it becomes as good as new. Let $X(t)$ be 0 if the machine is down at time t and 1 otherwise. Then, $\{X(t), t \geq 0\}$ is a CTMC with $S = \{0, 1\}$ and $v_0 = \lambda, v_1 = \mu, p_{01} = p_{10} = 1$. The rate matrix is

$$Q = \begin{bmatrix} -\lambda & \lambda \\ \mu & -\mu \end{bmatrix}.$$

The rate matrix is useful in analyzing the asymptotic behavior of a CTMC.

Furthermore, let S_n denote the time of the n th transition of a CTMC $\{X(t), t \geq 0\}$, and $Y_n = S_n - S_{n-1}$ be the n th sojourn time for $n \geq 1$ and $S_0 = 0$. Define $X_0 = X(0)$ as the initial state and $X_n = X(S_n+)$ as the state of the system immediately after the n th transition. The embedded process $\{X_0, (X_n, Y_n), n \geq 1\}$ satisfies

$$P\{X_{n+1} = j, Y_{n+1} > y | X_n = i, Y_n, X_{n-1}, Y_{n-1},$$

$$\dots, X_1, Y_1, X_0\} = p_{ij} e^{-v_i y}.$$

From the above equation, it is clear that $\{X_n, n \geq 0\}$ is a discrete-time Markov chain (DTMC). It is called the *embedded DTMC* of the CTMC $\{X(t), t \geq 0\}$. The transition matrix $P = [p_{ij}]$ of the embedded DTMC is connected to the rate matrix $Q = [q_{ij}]$ of the CTMC

$\{X(t), t \geq 0\}$ by the following equation:

$$p_{ij} = \begin{cases} q_{ij}/v_i & \text{if } v_i \neq 0, i \neq j, \\ 0 & \text{if } v_i \neq 0, i = j, \\ 0 & \text{if } v_i = 0, i \neq j, \\ 1 & \text{if } v_i = 0, i = j, \end{cases} \quad (1)$$

for $i, j \in S$. This relationship is useful in classifying the states of a CTMC, which in turn lets us to characterize the limiting distribution of a CTMC. The next section discusses the classification of states of a CTMC.

CLASSIFICATION OF STATES OF A CTMC

In this section, we introduce several concepts such as accessibility, communication, irreducibility, recurrence, and transience to classify the states of a CTMC. These concepts form the basis for understanding the asymptotic behavior of CTMCs.

State j is said to be *accessible* from state i if $p_{ij}(t) > 0$ for some $t \geq 0$. If state j is accessible from state i , we write $i \rightarrow j$. Two states i and j that are accessible to each other are said to *communicate*, and we denote this by $i \leftrightarrow j$. The relation of communication has reflexivity ($i \leftrightarrow i$), symmetry ($i \leftrightarrow j \Rightarrow j \leftrightarrow i$), and transitivity ($i \leftrightarrow j, j \leftrightarrow k \Rightarrow i \leftrightarrow k$) properties. A set $C \subset S$ is said to be a *communicating class* if (i) $i, j \in C \Rightarrow i \leftrightarrow j$, and (ii) $i \in C, i \leftrightarrow j \Rightarrow j \in C$. A communicating class C is said to be *closed* if $i \in C$ and $j \notin C$, and then j is not accessible from i . This implies that once a CTMC visits a state in a closed communicating class, it cannot leave that class of states. Hence, we can uniquely partition the state space of a DTMC as $S = C_1 \cup \dots \cup C_k \cup T$ where $C_1, \dots, C_k$ are k disjoint closed communicating classes and T includes the remaining states. A CTMC is said to be *irreducible* if all its states communicate with each other; otherwise, it is called *reducible*.

These definitions are the exact analogs of the corresponding definitions for DTMCs. Furthermore, while classifying the states of a CTMC, there is a one-to-one relationship between the CTMC $\{X(t), t \geq 0\}$ and the corresponding embedded DTMC $\{X_n, n \geq 0\}$. Using Equation (1), we can write the following statements:

1. $i \rightarrow j$ for $\{X(t), t \geq 0\}$ if and only if $i \rightarrow j$ for $\{X_n, n \geq 0\}$.
2. $i \leftrightarrow j$ for $\{X(t), t \geq 0\}$ if and only if $i \leftrightarrow j$ for $\{X_n, n \geq 0\}$.
3. C is a (closed) communicating class for $\{X(t), t \geq 0\}$ if and only if C is a (closed) communicating class for $\{X_n, n \geq 0\}$.
4. $\{X(t), t \geq 0\}$ is irreducible if and only if $\{X_n, n \geq 0\}$ is irreducible.

Therefore, the classification of the states of $\{X(t), t \geq 0\}$ is the same as that of the embedded DTMC $\{X_n, n \geq 0\}$. Next, we introduce the concepts of recurrence and transience. Let T_j denote the first time when the CTMC enters state $j, j \in S$. We can express T_j as follows:

$$T_j = \inf\{t \geq S_1 : X(t) = j\}, j \in S,$$

where $S_1 > 0$ is the first time that the CTMC changes state. We define

$$f_{ij} = P\{T_j < \infty | X(0) = i\} \quad (2)$$

as the probability that the CTMC eventually enters state j and $\mu_{ij} = E[T_j | X(0) = i]$ as the expected time it takes for the CTMC to enter state j starting from state i at time zero, $i, j \in S$. State i is said to be *recurrent* if $f_{ii} = 1$ and *transient* if $f_{ii} < 1$. On the basis of this definition, if state i is recurrent, starting in i , the CTMC will visit state i again. From the definition of a CTMC, the process will be starting over when it revisits state i , and hence, state i will eventually be visited again. Repeating this argument, we can conclude that if state i is recurrent, starting in state i , the CTMC will revisit state i infinitely often. On the other hand, if state i is transient, each time the CTMC visits state i , there is a positive probability of $1 - f_{ii}$ that it will never enter state i again. Hence, it follows that state i is recurrent if and only if, starting in state i , the expected number of times that the CTMC will visit state i is infinite. On the other hand, this expectation is finite for transient states. When $f_{ii} < 1$, it is clear that $\mu_{ii} = \infty$. However, if $f_{ii} = 1$, μ_{ii} can be infinite. A recurrent state i is said to be *positive recurrent* if $\mu_{ii} < \infty$ and *null recurrent* otherwise.

A state i is recurrent (transient) for a CTMC $\{X(t), t \geq 0\}$ if and only if it is recurrent

(transient) for the corresponding embedded DTMC $\{X_n, n \geq 0\}$. Therefore, recurrence and transience are class properties for CTMCs as they are for DTMCs. An irreducible CTMC is recurrent (transient) if and only if the embedded DTMC is irreducible and recurrent (transient).

On the other hand, for positive and null recurrence, there may not be a one-to-one correspondence between the CTMC and the embedded DTMC. More specifically, a state i can be positive recurrent for the CTMC while it is null recurrent for the embedded DTMC or vice versa. However, we can develop a necessary and sufficient condition for positive recurrence of CTMCs as follows: Suppose that $\{X(t), t \geq 0\}$ is an irreducible CTMC with a recurrent embedded DTMC $\{X_n, n \geq 0\}$ with transition probability matrix P and let π be a positive solution to $\pi = \pi P$. Then, the expected time between two consecutive visits to state j can be written as

$$\mu_{jj} = \frac{\sum_{i \in S} \pi_i / q_i}{\pi_j}, j \in S. \quad (3)$$

Hence, the CTMC is positive recurrent if and only if $\sum_{i \in S} \pi_i / q_i < \infty$.

In the remainder of this article, we will use the concepts introduced in this section to classify the CTMCs and analyze the asymptotic behavior based on this classification. We first present some general results as follows: Consider a CTMC $\{X(t), t \geq 0\}$ with a transition matrix $P(t)$. Regardless of the class properties of the CTMC, $P(t)$ always approaches a limit as $t \rightarrow \infty$. This limit can be computed as follows:

$$\lim_{t \rightarrow \infty} p_{ij}(t) = \frac{1}{q_j \mu_{jj}}, \quad (4)$$

for $j \in S$, and

$$\lim_{t \rightarrow \infty} p_{ij}(t) = \frac{f_{ij}}{q_j \mu_{jj}}, \quad (5)$$

for $i, j \in S$ and $i \neq j$. The intuition behind Equation (4) is as follows: The expected time that the CTMC spends in state j during each visit to this state is $1/q_j$. Recall that μ_{jj} is the expected time between two consecutive

visits to state j . Then, $1/q_j\mu_{jj}$ is the long-run fraction of time that the CTMC spends in state j when the starting state is j . Equivalently, it is also the long-run probability of finding the CTMC in state j when the starting state is j . If the starting state is $i \neq j$, then this probability is $f_{ij}/q_j\mu_{jj}$, which is given by Equation (5). If j is a transient or null-recurrent state of a CTMC, then $\lim_{t \rightarrow \infty} p_{ij}(t) = 0$ because $\mu_{jj} = \infty$. The next section discusses the asymptotic behavior of irreducible CTMCs.

ASYMPTOTIC BEHAVIOR OF IRREDUCIBLE CTMCs

An irreducible CTMC consists of a single closed communicating class of states. Hence, the states of such a CTMC can be all transient, or all null recurrent, or all positive recurrent. If an irreducible CTMC is transient or null recurrent, then $\lim_{t \rightarrow \infty} p_{ij}(t) = 0$ for all $i, j \in S$. A transient irreducible CTMC has an infinite state space. For $i \in S$, starting from state i , the expected number of times that state i is visited is finite. As a result, a transient irreducible CTMC will eventually permanently exit any state with probability 1 and the limiting distribution is zero. A null-recurrent irreducible CTMC also has an infinite state space. Unlike the transient case, each state of a null-recurrent CTMC will be visited infinitely often over the infinite horizon. However, the expected time between the two consecutive visits to each state is infinite. Thus, the limiting distribution is also zero for this case.

A positive recurrent irreducible CTMC is called *ergodic*. For an ergodic CTMC $\{X(t), t \geq 0\}$, the limiting distribution of $X(t)$ is independent of the initial state. Let us denote the limiting probability of being in state j by

$$p_j = \lim_{t \rightarrow \infty} P\{X(t) = j | X(0) = i\}, \quad j \in S,$$

and the limiting distribution by $p = [p_j]$. An irreducible CTMC is positive recurrent if and only if there exists a solution to the following

equations:

$$pQ = 0, \quad (6)$$

$$\sum_{j \in S} p_j = 1. \quad (7)$$

Furthermore, if there is a solution, it is unique. Equation (6) is known as the *balance equation*. If we write this equation in scalar form, we obtain the following set of equations:

$$\sum_{j \in S} p_i q_{ij} = \sum_{j \in S} p_j q_{ji} \text{ for } i \in S.$$

The left-hand side is the total rate of transitions out of state i and the right-hand side denotes the total rate of transitions into state i , $i \in S$. In steady state, these rates should be equal. Equation (7) is the *normalizing equation* as the sum of the limiting probabilities should be equal to 1.

An alternative way to compute the limiting distribution of a positive recurrent irreducible CTMC is to use the limiting distribution of the embedded DTMC. Let $\{X_n, n \geq 0\}$ be the embedded DTMC with a vector π satisfying $\pi = \pi P$ where P is the transition probability matrix. Combining Equations (3) and (5) and setting $f_{ij} = 1$ for $i, j \in S$ (because the CTMC is irreducible), we obtain

$$\lim_{t \rightarrow \infty} p_{ij}(t) = \frac{1/q_j}{\mu_{jj}} = \frac{\pi_j/q_j}{\sum_{k \in S} \pi_k/q_k}.$$

Since μ_{jj} denotes the expected time between two visits to state j and the expected time that the CTMC stays in state j is $1/q_j$, the above equation also denotes the fraction of time that the CTMC spends in state j , $j \in S$.

ASYMPTOTIC BEHAVIOR OF REDUCIBLE MARKOV CHAINS

Consider a reducible CTMC that consists of k closed communicating classes as $C_1, \dots, C_k$ and the remaining transient states form the set T . By relabeling the states of the CTMC

(if necessary), we can write the rate matrix as follows:

$$Q = \begin{bmatrix} Q(1) & & & 0 \\ & Q(2) & & \\ 0 & & \ddots & \\ & & & Q(k) \\ & R & & & Q(T) \end{bmatrix},$$

where $Q(r)$ denotes the rate matrix for the r th closed communicating class whose row sums are equal to zero, $r = 1, \dots, k$. $Q(T)$ is a $|T|$ by $|T|$ rate matrix with at least one row sum less than zero and R is a $|T|$ by $|S| - |T|$ non-negative matrix. Accordingly, the transition matrix $P(t)$ is given as follows:

$$P(t) = \begin{bmatrix} P_1(t) & & & 0 \\ & P_2(t) & & \\ 0 & & \ddots & \\ & & & P_k(t) \\ & P_R(t) & & & P_T(t) \end{bmatrix}.$$

Since $P_r(t)$ is the transition probability matrix of an irreducible CTMC, from the previous section, we know the asymptotic behavior of $P_r(t)$, $r = 1, \dots, k$. $\lim_{t \rightarrow \infty} P_T(t) \rightarrow 0$ since T is the set of transient states. Hence, in order to completely characterize the limiting behavior of $P(t)$, we need to investigate the limiting behavior of $P_R(t)$.

Define

$$\alpha_i(r) = P\{X(t) \in C_r \text{ for some } t \geq 0 \mid X(0) = i\},$$

$$i \in T, \text{ and } r = 1, \dots, k. \quad (8)$$

$\alpha_i(r)$ is the probability that starting from a transient state i , the probability that the CTMC eventually gets absorbed in class C_r . By using this definition, we can describe the asymptotic behavior of $P_R(t)$ as follows: If C_r is transient or null-recurrent $P_R(t)(i, j) = 0$ as $t \rightarrow \infty$ for $i \in T$ and $j \in C_r$. If C_r is positive recurrent, $P_R(t)(i, j) = \alpha_i(r)p_j$ as $t \rightarrow \infty$ for $i \in T$ and $j \in C_r$, where p_j is given by the solution to

$$p(r)Q(r) = 0, \sum_{j \in C_r} p_j = 1.$$

The probabilities $\{\alpha_i(r), i \in T\}$ defined by Equation (8) are given by the nonnegative solution to the following system of simultaneous linear equations:

$$\alpha_i(r) = \sum_{j \in C_r} \frac{q_{ij}}{q_i} + \sum_{j \in T, j \neq i} \frac{q_{ij}}{q_i} \alpha_j(r).$$

FURTHER READING

Analysis of the asymptotic behavior of CTMCs can be found in a number of textbooks on stochastic processes. Classical textbooks include those by Karlin and Taylor [1], Kulkarni [2,3], Resnick [4], and Ross [5,6]. In addition, since Markovian queueing systems are modeled as CTMCs, queueing theory books such as those by Gross and Harris [7], Kleinrock [8], and Medhi [9] also discuss the asymptotic behavior of CTMCs among others.

ASYMPTOTIC BEHAVIOR OF DISCRETE-TIME MARKOV CHAINS

EYLEM TEKIN

Department of Industrial and
Systems Engineering, Texas
A&M University, College
Station, Texas

INTRODUCTION

Markov chains have long been appropriate models for many real-life applications. Large number of physical, biological, and economic systems can be described by Markov chains. Examples include statistical mechanics, thermodynamics, genetics, sociology, telecommunication systems, computer systems, queueing systems, manufacturing and distribution systems, and pricing models among others.

Consider a system that can be in various states over time and transition from one state to the other occurs at discrete points in time randomly. Let X_n denote the state of the system at time $n = 0, 1, \dots$. $X_n, n \geq 0$, is a random variable that takes values in a set S , which is called the *state space*. The Markov property states that the future probability distribution of the system depends only on the current state and is independent of its past. That is, $P(X_{n+1} = j | X_n = i, X_{n-1} = i_{n-1}, \dots, X_0 = i_0) = P(X_{n+1} = j | X_n = i)$ for all $n \geq 0$ and $i, j, i_{n-1}, \dots, i_0 \in S$. The stochastic process $\{X_n, n \geq 0\}$ with Markov property is called a *discrete-time Markov chain* (DTMC). A DTMC $\{X_n, n \geq 0\}$ with state space S is called *time-homogenous* if $P(X_{n+1} = j | X_n = i) = P(X_1 = j | X_0 = i)$ for all $n \geq 0$. Andrey Markov, a Russian mathematician, introduced the concept of Markov chains and produced the first theoretical results in the beginning of the twentieth century [1,2].

DTMC models are useful in describing the future statistical properties of systems. In particular, the asymptotic behavior

of DTMCs is important in many applications. Several performance measures of practical interest can be computed by using the limiting distribution of X_n as $n \rightarrow \infty$. For example, in designing and operating queueing systems, these performance measures may include the average waiting time in queue, the average number waiting in queue, and server utilization. In telecommunication systems, the performance measures of interest can be the expected number of packets waiting in the buffer or the long-run fraction of time that the buffer is full. The asymptotic behavior of DTMCs is also relevant for the analysis of Markov decision processes [3], especially when the objective is to maximize (minimize) the long-run average reward (cost).

While studying the asymptotic behavior of a DTMC, the imminent questions that arise are: (i) Does the distribution of X_n approach a limit as $n \rightarrow \infty$?; (ii) If the limiting distribution exists, is it unique?; (iii) If there is a unique limiting distribution, how do we compute it? This article addresses these questions.

PRELIMINARIES

Consider a time-homogeneous DTMC $\{X_n, n \geq 0\}$ on state space $S = \{1, 2, \dots\}$ with one-step transition probability matrix $P = [p_{ij}]$ where

$$p_{ij} = P(X_{n+1} = j | X_n = i) \text{ for } i, j \in S \text{ and } n \geq 0.$$

We are interested in studying the behavior of X_n as $n \rightarrow \infty$. Since

$$P(X_n = j) = \sum_{i \in S} P(X_n = j | X_0 = i) P(X_0 = i),$$

$$i, j \in S \text{ and } n \geq 0, \quad (1)$$

the distribution of X_n depends on the initial distribution and the n -step

conditional probabilities of the DTMC. Let us define

$$p_{ij}^{(n)} = P(X_n = j | X_0 = i)$$

and denote the n -step transition probability matrix by $P^{(n)} = [p_{ij}^{(n)}]$ for $i, j \in S$ and $n \geq 0$. It can be shown that $P^{(n)} = P^n$ where P^n is the n th power of P . Letting $a_j^{(n)} = P(X_n = j)$ for $j \in S$ and the corresponding vector as $\mathbf{a}^{(n)} = [a_1^{(n)}, a_2^{(n)}, \dots]$ for $n \geq 0$, Equation (1) can be expressed in matrix-vector notation as

$$\mathbf{a}^{(n)} = \mathbf{a}^{(0)} P^n.$$

Hence, the asymptotic behavior of X_n depends on the asymptotic behavior of P^n .

Let us first define three types of distributions that are useful in analyzing the asymptotic behavior of X_n . The probability mass function of X_n as $n \rightarrow \infty$ is called the *limiting* or *steady-state* distribution, if it exists. We denote the limiting distribution by $\{\pi_j, j \in S\}$ where

$$\pi_j = \lim_{n \rightarrow \infty} P(X_n = j), j \in S.$$

The limiting distribution may not exist for all DTMCs. However, if a limiting distribution exists, it satisfies

$$\pi_j = \sum_{i \in S} \pi_i p_{ij}, j \in S, \quad (2)$$

$$\sum_{j \in S} \pi_j = 1. \quad (3)$$

Equation (2) is known as the *balance equation* since it balances the limiting probability of entering a state with the limiting probability of exiting that state. Equation (3) is the *normalizing equation* as the sum of the limiting probabilities over the state space should be equal to 1.

Next, a distribution $\{\pi_j^*, j \in S\}$ is called a *stationary* distribution, if

$$\begin{aligned} P(X_0 = j) &= \pi_j^* \text{ for } j \in S \Rightarrow \\ P(X_n = j) &= \pi_j^* \text{ for } j \in S \text{ and } n \geq 0. \end{aligned}$$

If the initial distribution of the DTMC is chosen as the stationary distribution, the distribution of it stays the same for all time periods. Stationary distribution may not exist for all DTMCs as well. On the other hand, $\{\pi_j^*, j \in S\}$ is a stationary distribution if and only if it satisfies the balance and normalizing equations given in Equations (2) and (3), respectively. Hence, a limiting distribution, when it exists, is also a stationary distribution.

There is also one more interpretation of the balance and the normalizing equations. Let us denote the expected number of times that state j is visited over a time span of $\{0, 1, \dots, n\}$ starting from state i by $m_{ij}(n)$ for $i, j \in S$. It can be shown that

$$m_{ij}(n) = \sum_{k=0}^n p_{ij}^{(k)}, i, j \in S \text{ and } n \geq 0, \quad (4)$$

and $M(n) = [m_{ij}(n)]$ is called the *occupancy time matrix*. Then, the limit of $m_{ij}(n)/(n+1)$ as $n \rightarrow \infty$ is the long-run fraction of time that the DTMC spends in state j starting from state i . Let us denote the long-run fraction of time that the DTMC spends in state j by $\hat{\pi}_j$. Then, we can define the *occupancy* distribution as $\{\hat{\pi}_j, j \in S\}$. If the occupancy distribution exists, it also satisfies Equations (2) and (3).

Thus, the normalized solution to the balance equations may have three different interpretations as limiting, stationary, and occupancy distributions. In the next sections, we will use these distributions to discuss the asymptotic behavior of DTMCs. The existence and uniqueness of these distributions are based on several characteristics of the DTMC. Next section describes these characteristics, which are essential in classifying DTMCs.

CLASSIFICATION OF STATES OF A DTMC

In this section, we introduce several concepts for classifying the states of a DTMC. These concepts form the basis for understanding the asymptotic behavior of DTMCs.

We begin with the following definitions: State j is said to be *accessible* from state i ,

if $p_{ij}^{(n)} > 0$ for some $n \geq 0$. This implies that state j is accessible from state i if and only if starting in i , it is possible that the system will ever enter state j . Two states i and j that are accessible to each other are said to *communicate*, and we denote this by $i \leftrightarrow j$. Note that each state communicates with itself since $p_{ii}^{(0)} = 1$. The relation of communication has reflexivity ($i \leftrightarrow i$), symmetry ($i \leftrightarrow j \Leftrightarrow j \leftrightarrow i$), and transitivity ($i \leftrightarrow j, j \leftrightarrow k \Rightarrow i \leftrightarrow k$) properties.

A set $C \subset S$ is said to be a *communicating class* if (i) $i, j \in C \Rightarrow i \leftrightarrow j$, and (ii) $i \in C, i \leftrightarrow j \Rightarrow j \in C$. A communicating class C is said to be *closed* if $i \in C$ and $j \notin C$, then j is not accessible from i . This implies that once a DTMC visits a state in a closed communicating class, it cannot leave that class of states. Hence, we can uniquely partition the state space of a DTMC as $S = C_1 \cup \dots \cup C_k \cup T$ where $C_1, \dots, C_k$ are k disjoint closed communicating classes and T includes the remaining states. A DTMC is said to be *irreducible* if S is a closed communicating class; otherwise, it is called *reducible*. In other words, an irreducible DTMC has only one class (i.e., all states communicate with each other).

Consider a three-state DTMC with the following one-step transition probability matrix:

$$P = \begin{bmatrix} \alpha & 1 - \alpha & 0 \\ \beta & \beta' & 1 - \beta - \beta' \\ 0 & \gamma & 1 - \gamma \end{bmatrix}. \quad (5)$$

In the above matrix, when $0 < \alpha, \beta, \beta', \gamma < 1$, and $\beta + \beta' < 1$, the DTMC is irreducible. For example, it is possible to go from state 1 to state 3 since $1 \rightarrow 2 \rightarrow 3$. On the other hand, when $\alpha = 1$, $0 < \beta, \beta', \gamma < 1$, and $\beta + \beta' < 1$, the DTMC is reducible. $C_1 = \{1\}$ is a closed communicating class. $T = \{2, 3\}$ is a communicating class that is not closed. Note that a finite-state DTMC has at least one closed communicating class, whereas a DTMC with an infinite state space may not necessarily have any closed communicating classes.

Next, we introduce the concepts of recurrence and transience. For any state i , let f_i denote the probability that, starting in state i , the DTMC will ever revisit state

i . State i is said to be *recurrent* if $f_i = 1$ and *transient* if $f_i < 1$. Based on this definition, if state i is recurrent, starting in i , the DTMC will eventually visit state i again. From the definition of a DTMC, the process will be starting over when it revisits state i , and hence, state i will eventually be visited again. Repeating this argument, we can conclude that if state i is recurrent, starting in state i , the DTMC will revisit state i infinitely often. On the other hand, if state i is transient, each time the DTMC visits state i , there is a positive probability of $1 - f_i$ that it will never enter state i again. Therefore, starting in state i , the probability that the DTMC is in state i for n time periods is $f_i^{n-1}(1 - f_i)$ for $n \geq 1$. In other words, starting in state i , the number of times that the DTMC will visit state i has a geometric distribution with a finite mean of $1/(1 - f_i)$. Hence, it follows that state i is recurrent if and only if starting in state i , the expected number of times that the DTMC will visit state i is infinite. On the other hand, this expectation is finite for transient states. That is, state i is recurrent (transient) if and only if

$$m_{ii}(\infty) = \sum_{n=0}^{\infty} p_{ii}^{(n)} = \infty (< \infty).$$

where $m_{ij}(n)$ is given by Equation (4) for $i, j \in S$ and $n \geq 0$.

Let us define T_i as the expected time between the two consecutive visits of the DTMC to state i . When $f_i < 1$, it is clear that $T_i = \infty$. However, T_i can be infinite even if $f_i = 1$. A recurrent state i is said to be *positive recurrent* if $T_i < \infty$ and *null recurrent* otherwise. A necessary and sufficient condition for positive and null recurrence can be given as follows: A recurrent state i is positive recurrent (null recurrent) if and only if

$$\lim_{n \rightarrow \infty} \frac{m_{ii}(n)}{n + 1} = \frac{1}{T_i} > 0 (= 0).$$

The above limit can be interpreted as the long-run fraction of time that the DTMC spends in state i .

Recurrence and transience are class properties. More specifically, if $i \leftrightarrow j$ and

i is transient (positive recurrent, null recurrent), then j is transient (positive recurrent, null recurrent). This observation greatly simplifies the task of identifying recurrent and transient states in a DTMC. In a communicating class, if one state is shown to be transient (positive recurrent, null recurrent), then all the remaining states have the same property. Furthermore, a finite communicating class is positive recurrent if it is closed and transient if not. Note that in a finite-state DTMC, not all states can be transient.

The last concept that we will discuss in this section is periodicity. A state i is said to have *period* d if $p_{ii}^{(n)} = 0$ whenever n is not divisible by d , and d is the largest integer with this property. This implies that if state i has period d , then $p_{ii}^{(nd)} > 0$ for $n \geq 0$. A state with period 1 is said to be *aperiodic*. Suppose the set of integers n for which $p_{ii}^{(n)} > 0$ is $\{0, 2, 5, 7, \dots\}$, then state i is aperiodic (i.e., $d = 1$). If this set is $\{0, 2, 4, 6, \dots\}$, then state i is periodic with period 2. If the DTMC never comes back to state i after leaving it (i.e., state i is transient or null recurrent), the period is ∞ . In such cases, periodicity is irrelevant. Periodicity is also a class property. That is, if state i has period d and it communicates with state j , then state j has also period d .

In the remainder of this article, we will use the concepts introduced in this section to classify the DTMCs and analyze the asymptotic behavior based on this classification. Next section presents the asymptotic behavior of irreducible DTMCs.

ASYMPTOTIC BEHAVIOR OF IRREDUCIBLE DTMCs

An irreducible DTMC consists of a single closed communicating class of states. Hence, the states of such a DTMC can be all transient, or all null recurrent, or all positive recurrent. If all states are positive recurrent, the irreducible DTMC can be further classified as either positive recurrent aperiodic or positive recurrent periodic. Recall that periodicity is not relevant when the DTMC is transient or null recurrent. Therefore, in this section, we consider the following four cases:

the DTMC is transient, null recurrent, aperiodic positive recurrent, and periodic positive recurrent.

We first state an important result related to the convergence of the limiting distribution in irreducible DTMCs. For an irreducible DTMC, if state i has period $d \geq 1$,

$$\lim_{n \rightarrow \infty} p_{ii}^{(nd)} = \frac{d}{T_i}, \quad i \in S. \quad (6)$$

Intuitively, in the aperiodic case, the DTMC visits state i in every T_i time periods in the long-run. For the periodic case (i.e., $d > 1$), Equation (6) follows from the fact that state i is visited at times that are integer multiples of period d . These convergence results can be shown by using the discrete renewal theorem [4,5].

The Transient Case

A transient irreducible DTMC has an infinite state space. For $i \in S$, starting from state i , the expected number of times that state i is visited is finite (i.e., $m_{ii}^{(n)} < \infty$). This implies that $\lim_{n \rightarrow \infty} p_{ii}^{(n)} = 0$ for $i \in S$. By using the Chapman–Kolmogorov equations [6], it is also straightforward to show that $\lim_{n \rightarrow \infty} p_{ij}^{(n)} = 0$ for $i, j \in S$. As a result, a transient irreducible DTMC will eventually permanently exit any state with probability 1 and the limiting distribution is zero.

The Null Recurrent Case

A null recurrent irreducible DTMC also has an infinite state space. Unlike the transient case, each state of a null recurrent DTMC will be visited infinitely often over the infinite horizon. However, the expected time between the two consecutive visits to each state is infinite. Thus, the limiting distribution is also zero for this case.

The Positive Recurrent Case

An irreducible DTMC is positive recurrent if and only if there exists a solution to the balance and normalizing equations given by Equations (2) and (3), respectively. Furthermore, if there is a solution, it is unique. We will first discuss the case where such a DTMC is also aperiodic.

a) The Aperiodic Case

An aperiodic positive recurrent irreducible DTMC is called *ergodic*. For an ergodic DTMC, $\lim_{n \rightarrow \infty} p_{ij}^{(n)}$ exists, and it is independent of the starting state i . That is, the limiting probability of state j is given by

$$\pi_j = \lim_{n \rightarrow \infty} p_{ij}^{(n)} = \lim_{n \rightarrow \infty} p_{jj}^{(n)} = \frac{1}{T_j}, \quad i, j \in S,$$

where the second equality follows from Equation (6). Furthermore, $\{\pi_j, j \in S\}$ is the unique solution to the balance and normalizing equations given by Equations (2) and (3), respectively. In this case, limiting distribution is the same as the stationary and occupancy distributions.

Consider the transition probability matrix given in Equation (5) with $\alpha = 0.4$, $\beta = 0.2$, $\beta' = 0$, and $\gamma = 0.6$. It is straightforward to observe that the DTMC that corresponds to P is ergodic. Computing the limit of P^n and $M(n)/(n+1)$ as $n \rightarrow \infty$, we obtain

$$\begin{aligned} \lim_{n \rightarrow \infty} P^n &= \lim_{n \rightarrow \infty} \frac{M(n)}{n+1} \\ &= \begin{bmatrix} 0.125 & 0.5 & 0.375 \\ 0.125 & 0.5 & 0.375 \\ 0.125 & 0.5 & 0.375 \end{bmatrix}. \end{aligned}$$

The limiting and occupancy distributions coincide and independent of the starting state (i.e., the rows of the limiting matrix are the same). If we also solve the normalized balance equations, we get $\pi_1 = 0.125$, $\pi_2 = 0.5$, and $\pi_3 = 0.375$.

b) The Periodic Case

For an irreducible positive recurrent DTMC with period $d > 1$, $\lim_{n \rightarrow \infty} p_{ij}^{(n)}$ does not exist. However, since $T_j < \infty$, from Equation (6), we have

$$\lim_{n \rightarrow \infty} p_{ij}^{(nd)} = \frac{d}{T_j} = d\hat{\pi}_j > 0, \quad j \in S.$$

Hence, the limit of $p_{ij}^{(n)}$ does not exist as $n \rightarrow \infty$ and only d equidistant subsequences of $p_{ij}^{(n)}$ (i.e., $p_{ij}^{(0)}, p_{ij}^{(d)}, p_{ij}^{(2d)}, \dots$) have limits. On

the other hand, the limit for $m_{ij}(n)/(n+1)$ exists as $n \rightarrow \infty$ and is given by

$$\lim_{n \rightarrow \infty} \frac{m_{ij}(n)}{n+1} = \hat{\pi}_j, \quad i, j \in S. \quad (7)$$

The $\{\hat{\pi}_j, j \in S\}$ in Equation (7) is the occupancy distribution and given by the unique solution to the balance and normalizing equations (2) and (3), respectively.

Consider the transition probability matrix given in Equation (5) with $\alpha, \beta' = 0$, $\beta = 0.2$, and $\gamma = 1$. In this case, the underlying DTMC is positive recurrent irreducible with a period of 2. Computing the powers of P , we observe that

$$\begin{aligned} P^{2n} &= \begin{bmatrix} 0.2 & 0 & 0.8 \\ 0 & 1 & 0 \\ 0.2 & 0 & 0.8 \end{bmatrix}, \quad \text{for } n \geq 1 \text{ and} \\ P^{2n+1} &= \begin{bmatrix} 0 & 1 & 0 \\ 0.2 & 0 & 0.8 \\ 0 & 1 & 0 \end{bmatrix}, \quad \text{for } n \geq 0. \end{aligned}$$

The value of $\{P^n, n \geq 0\}$ fluctuates, and hence, the limiting distribution does not exist. On the other hand,

$$\lim_{n \rightarrow \infty} \frac{M(n)}{n+1} = \begin{bmatrix} 0.1 & 0.5 & 0.4 \\ 0.1 & 0.5 & 0.4 \\ 0.1 & 0.5 & 0.4 \end{bmatrix}.$$

Thus, the occupancy distribution exists and is independent of the initial state. The long-run fraction of time that the DTMC spends in states 1, 2, 3 are $\hat{\pi}_1 = 0.1$, $\hat{\pi}_2 = 0.5$, and $\hat{\pi}_3 = 0.4$, respectively. This distribution can also be computed by solving the normalized balance equations.

To summarize, the balance and the normalizing equations play a key role in analyzing the asymptotic behavior of irreducible DTMCs. If there is a solution to these equations, this always indicates that the DTMC is recurrent. However, the interpretation of the solution is different based on the periodicity of the DTMC. When the DTMC is aperiodic, the solution to the normalized balance equations can be interpreted as (i) the limiting probability of being in state j , or (ii) the stationary probability of being in

state j , or (iii) the long-run fraction of time that the DTMC spends in state j . When the DTMC is periodic, only interpretations (ii) and (iii) remain valid.

ASYMPTOTIC BEHAVIOR OF REDUCIBLE MARKOV CHAINS

When the DTMC is reducible, the balance and the normalizing equations either do not have a solution or have infinitely many solutions. For example, consider the transition probability matrix given in Equation (5) with $\alpha = \beta = \beta' = \gamma = 0$. For this DTMC with two transient and one recurrent communication classes, the normalized balance equations do not have a solution. On the other hand, consider that $\alpha, \beta, \gamma = 0$ and $\beta' = 1$, which results in $p_{ii} = 1$ for $i = 1, 2, 3$. In this case, there are infinitely many solutions to the normalized balance equations.

Consider a reducible DTMC that consists of k closed communicating classes as $C_1, \dots, C_k$ and the remaining transient states form the set T . By relabeling the states of the DTMC (if necessary), we can write the transition probability matrix as follows:

$$P = \begin{bmatrix} P(1) & & & 0 \\ & P(2) & & \\ 0 & & \ddots & \\ & & & P(k) \\ & D & & & Q \end{bmatrix}, \quad (8)$$

where $P(r)$ denotes the transition probability matrix for the r th closed communicating class, $r = 1, \dots, k$, and D and Q are the matrices that give the transition probabilities from transient states to recurrent and transient states, respectively. The n th power of P is

given as follows:

$$P^n = \begin{bmatrix} P^n(1) & & & 0 \\ & P^n(2) & & \\ 0 & & \ddots & \\ & & & P^n(k) \\ & D_n & & & Q^n \end{bmatrix}. \quad (9)$$

Since $P(r)$ is the transition probability matrix of an irreducible DTMC, from the previous section, we know the asymptotic behavior of $P^n(r)$, $r = 1, \dots, k$. $\lim_{n \rightarrow \infty} Q^n \rightarrow 0$ as T is the set of transient states. Hence, in order to completely characterize the limiting behavior of P^n we need to investigate the limiting behavior of D_n .

Define

$$\alpha_i(r) = P(X_n \in C_r \text{ for some } n > 0 | X_0 = i),$$

$$i \in T \text{ and } r = 1, \dots, k. \quad (10)$$

where $\alpha_i(r)$ is the probability that starting from a transient state i , the probability that the DTMC eventually gets absorbed in class C_r . By using this definition, we can describe the asymptotic behavior of D_n as follows: If C_r is transient or null recurrent $D_n(i, j) = 0$ as $n \rightarrow \infty$. If C_r is positive recurrent and aperiodic, $D_n(i, j) = \alpha_i(r)\pi_j$ as $n \rightarrow \infty$ where π_j is given by the solution to

$$\pi_j = \sum_{l \in C_r} \pi_l p_{lj}, \quad j \in C_r, \quad (11)$$

$$\sum_{l \in C_r} \pi_l = 1.$$

If C_r is positive recurrent and periodic, $D_n(i, j)$ does not have a limit as $n \rightarrow \infty$. However,

$$\lim_{n \rightarrow \infty} \frac{1}{n+1} \sum_{l=0}^n D_l(i, j) = \alpha_i(r)\pi_j, \quad j \in C_r,$$

where π_j is the solution to Equation (11).

FURTHER READING

Analysis of the asymptotic behavior of DTMCs can be found in a number of textbooks on stochastic processes. Classical textbooks include Karlin and Taylor [4], Kulkarni [7,8], Resnick [9], and Ross [6,10]. In addition to the theoretical foundations, Kulkarni [7] also provides computational algorithms for (i) determining recurrent and transient states in infinite state DTMCs, (ii) determining the period of a state, and (iii) evaluating the limiting distribution for irreducible DTMCs.

INTRODUCTION

The Austrian Society of Operations Research [Oesterreichische Gesellschaft fuer Operations Research (OEGOR)] is a non-profit scientific organization which supports the application and promotes development of operations research (OR) methods in Austria, with particular focus on efficient knowledge transfer among high-profile scientific research and decision makers in all areas. As a nationwide association, OEGOR also represents Austria in the international network of OR experts such as the Association of European Operational Research Societies (EURO) and the International Federation of Operational Research Societies (IFORS).

History and Milestones

OEGOR's predecessor was the Austrian working group on Operations Research (OEAGOR) which was founded by Prof. Christoph Mandl from the Institute for Advanced Studies (IHS). Erich Steinbauer from IBM Austria, who developed the first professional optimization system for power plants in Europe, was as a very active member during those first years. In the mid-1970s, Prof. Mikulas Luptacik moved from the IHS to the Institute of Operations

Research at the Vienna University of Technology. He spread the idea of establishing an Austrian Society of Operations Research. This is why, in fall 1978, OEGOR the OEGOR was founded at the Vienna University of Technology. First executive board members included: Prof. Gustav Feichtinger (Vienna University of Technology), Prof. Otto Gurtner (University of Natural Resources and Applied Life Sciences, Vienna), Peter Harhammer (IBM), Rainer Hasenauer (Institute for Advanced Studies), Alfred Kalliauer (Verbund), Christoph Mandl (Institute for Advanced Studies), Georg Urbanski (Austrian Airlines), and Prof. Guenther Vinek (University of Vienna). Christoph Mandl became OEGOR's founding president.

Shortly after, Christoph Mandl moved to Boston for his research stay at the Operations Research Center at the M.I.T. His successor, Peter Harhammer from IBM, presided over the OEGOR till 1986. He intensified contacts to fellow societies and organized the EURO VI Conference in Vienna in July 1983. Furthermore, he included many practitioners from the energy industry, especially in the working group on optimization and prognosis.

During the presidency of Prof. Rainer Burkard from the Technical University of Graz (1986–1988), a joint meeting with the Swiss Society of Operations Research (SVOR) was organized in July 1987, which proved to be a milestone for future collaboration between Switzerland and Austria. In 1997, Prof. Burkard was awarded the EURO Gold Medal in honor of his outstanding research in combinatorial optimization. He is a frequently invited keynote speaker at international conferences such as the EURO Bonn Meeting in 2009.

His successor, Prof. Gustav Feichtinger from the Vienna University of Technology, Department of Operations Research (1988–1991) successfully organized the huge OR 1990 Conference at the Vienna University of Technology and the Vienna University of Economics and Business, together with his

colleagues (Richard Hartl, Wolfgang Janko, Wolfgang Katzenberger, Adolf Stepan, Alfred Taudes, Alfred Wagenhofer). The conference budget amounted to more than € 300,000, but fortunately many sponsors could be found. With more than 1,200 participants and many distinguished keynote speakers, this event constituted an important milestone for our society. Prof. Feichtinger became an honorary member of both the Austrian and the German Societies of OR. His recent retirement came as a terrible blow to our society and especially to his well-established research group on optimal control theory, especially applied to socio-economic decision problems.

Prof. Wolfgang Katzenberger from the Vienna University of Technology took over the presidency for a few months before Prof. Georg Pflug from the University of Vienna (Department of Statistics and Decision Support Systems) was elected the next president for 1992–1993. In May 1993, under President Pflug, OEGOR finalized and published a comprehensive Software Guide on OR. Furthermore, Pflug intensively recruited new members from industry and academia so that the membership rose to 165. Prof. Mikulas Luptacik took a major part in launching OEGOR's scientific journal, the *Central European Journal for Operations Research and Economics (CEJORE)* during the presidency of Prof. Pflug. *CEJORE* was a successor of the *Czechoslovakian Journal for Operations Research (CSJOR)* published by Kartprint in Bratislava. Prof. Pflug is still very actively involved in the editorial board of this journal. Currently, he is serving as dean of the Faculty of Business, Economics, and Statistics, University of Vienna, Austria and as head of the OEGOR working group on OR in finance. His main research interests lie in computational risk management and he has many successful industrial applications in this field.

Under President of Prof. Ulrike Leopold-Wildburger from the University of Graz, Department for Statistics and Operations Research (1993–1997), the journal *CEJORE* became scientifically and financially well-established. Thanks to her great efforts, our fellow societies of Croatia, Czech Republic,

Hungary, Slovakia, and Slovenia joined this project. In the following years, she continued putting a lot of effort into the journal. She established a laboratory for experimental research and collaborates with internationally respected international scientists such as Prof. Reinhard Selten, a Nobel laureate. In 2008, she was awarded the Great Josef Krainer Prize for Science and Research.

OEGOR's next president was Prof. Mikulas Luptacik from the Vienna University of Technology, Department of Operations Research (1997–1999). Together with Ulrike Leopold-Wildburger, they worked hard on establishing a sound financial basis for the journal *CEJORE* to minimize the resulting financial risks for the OEGOR. In the course of this process, *CEJORE* was renamed to *Central European Journal for Operations Research (CEJOR)*. Today, *CEJOR* is published by Springer and is also ranked in the Science Citation Index (SCI). Currently, Prof. Luptacik is a full professor for Quantitative Economics at the Vienna University of Economics and Business Administration with a main research interest in data envelopment analysis. Furthermore, he is the head of the Industrial Science Institute, Vienna.

Under President Prof. Richard Hartl from the University of Vienna, Department of Production and Logistics (1999–2003), OEGOR launched its Internet website [1] and published its first electronic newsletter. Furthermore, Prof. Franz Rendl from the University of Klagenfurt (Department of Mathematics) organized the OR 2002 Conference, a joint meeting of the Austrian, German, and Swiss Operations Research Societies. For several years, Prof. Hartl served as managing editor of the *OR Spectrum*, one of the journals of the German OR society. He established a strong working group on ant colony optimization and heuristics at the University of Vienna, which are applied in industry and health care, such as ambulance vehicle routing and location for the Austrian Red Cross.

Prof. Immanuel Bomze from the University of Vienna, Department of Statistics and Decision Support (2003–2006) was the next president. He improved OEGOR's webpage by improving content and database management. Furthermore, he intensified

the contacts to practitioners and drew up OEGOR's new statutes. During his presidency, Bank Austria started the sponsorship for the OEGOR prize for young researchers. His research interests are, among others, asymptotic statistics and stochastic modeling, optimization theory, and applications of dynamical systems such as in telecommunication for Telekom Austria. Prof. Bomze serves as head of the OEGOR working group on the theory and practice of optimization.

In 2006, Prof. Marion Rauner from the University of Vienna, Department of Innovation and Technology Management was elected president. The webpage of the society was further improved. In fall 2008, the OEGOR celebrated its 30th anniversary in the old City Hall, an event sponsored by EURO, Bank Austria, the City of Vienna, the University of Vienna, Austrian Telecom, and fin4cast. Fellow societies congratulated OEGOR on its achievements and prolonged their cooperation and financial contributions to our joint journal CEJOR. The neighbor societies have continued their cooperation and financial contribution regarding our joint journal CEJOR. We certainly had reason to celebrate because CEJOR was included in the SCI—a major accomplishment of **editor-in-chief** Prof. Leopold-Wildburger who was supported by **editor-in-chiefs** Profs. Luptacik, Prof. Pflug, and Prof. Vetschera. Prof. Rauner serves as head of the OEGOR working group on health care. She was presented, amongst others, the Pharmig Prize for Health Economics in 2002 for her research on the evaluation of external defibrillators for the Austrian Red Cross together with her masters student, Nikolaus Bajmoczy. Her main research focus is on health technology assessment, prevention policy models, and in-patient reimbursement systems.

Current Organization of the Austrian OR Society

In 2008, the new executive board of OEGOR was elected:

- Prof. Marion Rauner (University of Vienna)—president;

- Prof. Eranda Dragoti-Cela (Technical University of Graz)—OEGOR news;
- Florian Frommlet (University of Vienna)—external communication;
- Josef Haunschmied (Vienna University of Technology)—secretary, promotion of young scientists;
- Georg Kern (Telekom Austria)—vice treasurer, sponsoring;
- Martin Kuehrer (fin4cast)—vice president, sponsoring;
- Gerold Petritsch (e&t Energy Trading Company)—treasurer; and
- Prof. Franz Rendl (University of Klagenfurt)—vice secretary, CEJOR executive.

OEGOR focuses on these main topics:

- supply chain management;
- trans-business logistics-controlling;
- methods and software for production planning;
- efficiency and productivity analysis for industry, commerce, and non-profit organizations;
- financial engineering;
- telecommunication.

These topics are discussed both at the annual meetings and at regular meetings of the different working groups throughout the year. The current working groups of OEGOR include:

- Metaheuristics—Head: Prof. Peter Greistorfer (University of Graz);
- OR in Finance—Heads: Prof. Georg Pflug (University of Vienna) and Martin Kuehrer (fin4cast);
- OR in Health Care—Heads: Prof. Marion Rauner (University of Vienna) and Prof. Margit Sommersguter-Reichmann (University of Graz);
- Production and Logistics—Head: Prof. Manfred Gronalt (University of Natural Resources and Applied Life Sciences, Vienna) and Prof. Werner Jammerneegg (Vienna University of Economics and Business);

- Theory and Practice of Optimization—Head: Prof. Immanuel Bomze (University of Vienna); and
- Mathematical Economics and Optimization in Energy—Head: Gerold Petritsch (e&t, Energy Trading Company).

OEGOR actively collaborates with fellow OR societies and EURO. This is reflected in joint meetings of working groups (e.g., Vienna, Austria, 2005; Graz, Austria, 2007; Neubiberg, Germany, 2007) and joint conferences of the Austrian, German, and Swiss OR Societies (e.g., Klagenfurt, Austria, 2002; Karlsruhe, Germany, 2007; Zuerich, Switzerland, 2011). Furthermore, OEGOR frequently invites distinguished OR specialists to contribute in theory excellence in theory and practice to our working groups. Prof. Ulrike Leopold-Wildburger from the University of Graz, Austria and Prof. Stefan Pickl from the University of Armed Forces, Munich (Neubiberg), Germany chair the EURO working group on Experimental Economics (EWG E-CUBE). In addition, several Austrian researchers are involved in the board of EURO working groups. We are also proud that Prof. Franz Rendl from the University of Klagenfurt will organize a European Summer Institute (ESI) on non-linear methods in combinatorial optimization for EURO in September 2010.

Supporting young scientists is particularly important to our society. Since 1985, many young scientists have been awarded OEGOR prizes which are partly sponsored by, for example, Bank Austria. Many laureates have become associate or full professors at Austrian and foreign universities. For example, Guenter Rote received the OEGOR prize in 1985 for his master thesis on “A systolic array algorithm for the algebraic path problem” written under the supervision of Prof. Rainer Burkard at the TU Graz.

He is currently full professor for computer science at the Free University of Berlin. Herbert Dawid was awarded the OEGOR prize in 1995 for his PhD thesis on genetic learning in economic systems, which he wrote while working as an assistant at the Vienna University of Technology, Department of Operations Research. He is now a distinguished professor at the University of Bielefeld, Department of Mathematical Economics in Germany. OEGOR laureate of 2003 was Marc Reimann, who worked at the Department of Production and Logistics at the University of Vienna, and wrote his PhD thesis on “An ant-based optimization of goods transportation.” He worked at the Department of Production and Logistics at the University of Vienna. In 2009, he was appointed full professor for production and logistics at the University of Graz in Austria. Apart from this, we also sponsor young scientists so as to enable them to participate in winter and summer courses on OR and quantitative modeling.

OEGOR cooperates with fellow OR societies from Czech Republic, Hungary, Slovakia, Slovenia, and Croatia to editing and finance the SCI-indexed journal CEJOR, which is published by Springer. In addition, members of the Austrian OR Society publish scientific books, work as editors of internationally renowned journals, and edit special issues on different topics for OR journals.

Acknowledgment

The authors wish to acknowledge constructive comments on a previous version of this paper made by OEGOR members (especially Prof. Bettina Klinz, Gabriela Sturm-Petritsch, and Gerold Petritsch).

AVAILABILITY ANALYSIS: CONCEPTS AND METHODS

ENRICO ZIO
Ecole Centrale Paris-Supelec,
Paris, France

Politecnico di Milano, Milano,
Italy

Availability is a concept used to characterize the performance of a machine or component (hereafter more generally termed *unit*) with respect to its ability to fulfill the function for which it is operated [1–6]. It applies to units that can be maintained, restored to operation, or renovated upon failure depending on the particular strategy adopted to optimally assure its function:

- off-schedule (corrective) maintenance, that is, replacement or repair of the failed unit;
- preventive maintenance, that is, regular inspections, and possibly repair, based on a structured maintenance plan;
- conditioned maintenance, that is, performance of repair actions upon detection of the degraded conditions of the unit.

It differs from the reliability indicator used to characterize the ability of a unit of achieving the objectives of a specified mission, without failures, within an assigned period (see also the section titled “Reliability and Maintainability” in this encyclopedia).

The main issues to consider when analyzing the availability of a unit are as follows:

1. *Unrevealed failures*, that is, when a unit fails unnoticed; the system goes on without noticing the unit failure until a test on the unit is made or the unit is demanded to function.

2. *Testing/preventive maintenance actions*, that is, when a unit is removed from the system for testing or preventive maintenance.
3. *Repairs*, that is, when a unit is unavailable because under repair.

In this chapter, a general introduction to the quantitative modeling for the availability analysis of components and systems is provided.

AVAILABILITY: QUANTITATIVE DEFINITION

Let $X(t)$ be a binary indicator variable denoting the state of a unit at time t , that is, $X(t) = 1$ if the unit is operating at time t and $X(t) = 0$, if is failed at time t . The *instantaneous availability* $p(t)$ is defined as the probability that the system is operating at time t ; dually, the *unavailability* $q(t)$ is defined as the probability that the unit is failed at time t . Obviously, $p(t) = 1 - q(t)$.

Notice the difference in the meaning of $p(t)$, the probability that the unit is operating at time t , from that of the reliability $R(t)$, the probability that the unit functions free of failures up to time t (see also the section titled “Reliability and Maintainability” in this encyclopedia).

Operatively, the time-dependent availability function of a unit is synthesized by point values as follows:

- For units undergoing corrective maintenance, the *limiting* or *steady-state availability* is computed as the mathematical limit of the availability function $p(t)$ as t grows to infinity. It represents the probability that the unit is functioning at an arbitrary moment of time, after the transient of the failure and repair processes have stabilized. It is obviously undefined for units under periodic maintenance, for which the limit does not exist.

- For units under periodic maintenance, the average availability over a given period of time is introduced as the proper indicator of performance. It represents the expected proportion of time that the system is operating in the considered period of time.

The Availability of an Unattended Unit

An unattended unit (i.e., a unit whose operation is not monitored) will function till its first failure and remain failed after that, because unnoticed. Hence, the probability $p(t)$ that at time t the unit is functioning is equal to the probability that it never failed before t , that is, the reliability at time t .

The Availability of a Continuously Monitored Unit

For a continuously monitored unit it is assumed that restoration starts immediately after its failure and a probabilistic model describing the duration of the repair process is introduced.

Consider N identical units at time $t = 0$ and let $h(t)$ be the conditional probability density function of the unit random failure time given that it is operating at time t (hazard rate, see also **Hazard Rate Function**) and $g(t)$ the probability density function of the random repair duration. At any successive time t , some units will be functioning whereas others will be failed; the following balance equation for the expected number of units functioning at time $t + \Delta t$ can be written as follows:

$$\begin{aligned} N p(t + \Delta t) &= N p(t) - N p(t) h(t) \Delta t \\ &\quad + \int_0^t N p(\tau) h(\tau) \Delta \tau g(t - \tau) \Delta t. \end{aligned} \quad (1)$$

The first term on the right-hand side is the expected number of units functioning at time t ; the second term is the number of units failing in the interval Δt , that is, the loss term in the balance equation; the third term is the expected number of units that had failed prior to t in a generic interval $(\tau, \tau + \Delta \tau)$ and

whose restoration terminates in $(t, t + \Delta t)$, integrated over all values of $\tau \leq t$.

Dividing by $N \Delta t$, subtracting $p(t)$ on both sides, and letting Δt and $\Delta \tau$ tend to zero, the following integral-differential equation is obtained:

$$\begin{aligned} \frac{dp(t)}{dt} &= -h(t) p(t) \\ &\quad + \int_0^t h(\tau) p(\tau) g(t - \tau) d\tau, \end{aligned} \quad (2)$$

where the integral term on the right-hand side of the equation represents the convolution of the instantaneous availability function and the restoration probability density function.

As initial condition, it is usually assumed that the unit is functioning at the initial time $t = 0$, that is, $p(0) = 1$.

The solution to the integral-differential equation (Eq. 2) depends on the functional form of $h(t)$ and $g(t)$. One way to proceed is by applying the Laplace transform to obtain an algebraic equation in the transform $\tilde{p}(s)$ which is then inverse transformed to obtain $p(t)$ to which the final value theorem can be applied for obtaining the limiting availability, p_∞ . The Laplace transform of the probability $p(t)$ is defined as $\tilde{p}(s) = L[p(t)] = \int_0^\infty e^{-st} p(t) dt$.

Consider, for example, a unit with exponential probability distributions of the random failure time and repair duration, with rates λ and μ , respectively, that is, $h(t) = \lambda$ and $g(t) = \mu e^{-\mu t}$; the Laplace transform $\tilde{p}(s)$ of the availability is easily found to be

$$\tilde{p}(s) = \frac{1}{s + \lambda \frac{s}{s + \mu}} = \frac{s + \mu}{s(s + \mu + \lambda)}, \quad (3)$$

which can be inverted to obtain the instantaneous availability in the time domain:

$$p(t) = \frac{\mu}{\mu + \lambda} + \frac{\lambda}{\mu + \lambda} e^{-(\mu + \lambda)t}. \quad (4)$$

To determine the limiting availability, p_∞ , the final-value theorem can be applied

$$p_\infty = \lim_{t \rightarrow \infty} p(t) = \lim_{s \rightarrow 0} [s \tilde{p}(s)] = \frac{\mu}{\mu + \lambda} \quad (5)$$

or more simply, in this case, one may directly let t tend to zero in Equation (4).

Notice that one can also write Equation (5) as

$$p_{\infty} = \frac{\frac{1}{\lambda}}{\frac{1}{\lambda} + \frac{1}{\mu}} = \frac{\text{MTTF}}{\text{MTTF} + \text{MTTR}}, \quad (6)$$

where MTTF (Mean Time To Failure) and MTTR (Mean Time To Repair) are the expected values of the probability distributions of the unit failure and repair times.

The Availability of a Unit Under Periodic Test

Some types of units are operated in standby until they are called into operation. These units are unattended and their failure is revealed only when tested.

For a unit undergoing a periodic inspection and maintenance plan, the instantaneous availability is a periodic function of time that can be synthesized by the average availability over the period τ between successive inspections:

$$p_{\tau} = \frac{\int_0^{\tau} p(t) dt}{\tau} = \frac{\int_0^{\tau} R(t) dt}{\tau}, \quad (7)$$

where the unit instantaneous availability $p(t)$ is equal to its reliability $R(t)$ within the interval τ in which it is unattended. Notice that the testing and maintenance procedures have been assumed to occur instantaneously every τ and to bring the unit back to its perfect, *as good as new* conditions.

Dually, the average unavailability over the period τ is

$$q_{\tau} = \frac{\int_0^{\tau} q(t) dt}{\tau} = \frac{\int_0^{\tau} F(t) dt}{\tau}, \quad (8)$$

where $F(t) = 1 - R(t)$ is the cumulative distribution function of the unit failure times.

For example, if the unit has exponentially distributed failure times with constant rate λ , $F(t) = 1 - e^{-\lambda t}$, which for the practical cases of interest can be approximated as $F(t) = 1 -$

$e^{-\lambda t} \cong \lambda t$ so that the average unavailability takes the common form:

$$q_{\tau} = \frac{\int_0^{\tau} F(t) dt}{\tau} = \frac{\int_0^{\tau} \lambda t dt}{\tau} = \frac{1}{2} \lambda \tau. \quad (9)$$

Assuming a finite duration τ_R of the test operations, during which the unit is unavailable, the average availability over the entire testing cycle period $\tau + \tau_R$ becomes

$$\bar{p} = \frac{\int_0^{\tau} R(t) dt}{\tau + \tau_R}, \quad (10)$$

and the average unavailability

$$\bar{q} = \frac{\tau_R + \int_0^{\tau} F(t) dt}{\tau + \tau_R}. \quad (11)$$

However, typically in practice the duration τ_R is small compared with the period τ , so that

$$\bar{p} = \frac{\int_0^{\tau} R(t) dt}{\tau} \quad (12)$$

and

$$\bar{q} = \frac{\tau_R + \int_0^{\tau} F(t) dt}{\tau}. \quad (13)$$

AVAILABILITY OF COMPLEX SYSTEMS: MARKOV MODELING

When one is interested by the availability of a system made of many units in complex logic, the previous analysis must be extended to account for the system behavior as described by its multiple states and the transitions among them. The system states are defined by the states of the units comprising the system. The units are not restricted to having only two possible states but rather may have a number of different states such as functioning, in standby, degraded, partially failed, completely failed, and under maintenance; the various failure modes of a unit may also be defined as states. The transitions between

the states occur randomly in time, because caused by various mechanisms and activities such as failures, repairs, replacements, and switching operations, which are random in nature. Common cause failures may also be included as possible transitions occurring randomly in time.

Let us consider a system that may stay in $N + 1$ configurations, $j = 0, 1, 2, \dots, N$. The state variable describing the system configuration at time t is denoted by $X(t)$ and is no longer binary. The system is assumed to start in a specified state at time $t = 0$. The transitions between states are assumed to occur continuously in time as described by a stochastic process $\{X(t); t \geq 0\}$ governed by the transition probabilities.

Under specified conditions, the stochastic process of the system evolution may be described as a Markov process in which the system states and the possible transitions can be depicted with the aid of a state-space diagram, known as a Markov diagram and be mathematically described by a probabilistic Markov system of equations [7–12] (see also the section titled “Continuous-Time Markov Chain” in this encyclopedia). The Markov property states the following: given that a system is in state i at time t [i.e., $X(t) = i$], the probability of reaching state j at time $t + v$ does not depend on the states $X(u)$ visited by the system prior to t ($0 \leq u < t$). In other words, given the present state $X(t)$ of the system, its future behavior is independent of the past:

$$\begin{aligned} P[X(t+v)=j|X(t)=i, X(u)=x(u), 0 \leq u < t] \\ = P[X(t+v)=j|X(t)=i] \end{aligned} \quad (14)$$

The conditional probabilities

$$P[X(t+v)=j|X(t)=i] \quad i, j = 0, 1, 2, 3, \dots, N \quad (15)$$

are called the *transition probabilities* of the Markov process. If the transition probabilities do not depend on time t but only on the time interval v for the transition, then the Markov process is said to be homogeneous or

stationary:

$$\begin{aligned} P[X(t+v)=j|X(t)=i] &= p_{ij}(v), \\ \text{for } t, v > 0 \text{ and } i, j &= 0, 1, 2, \dots, N. \end{aligned} \quad (16)$$

A Markov process with stationary transition probabilities has no memory.

Considering a time step dt sufficiently small that only one event can occur, it is possible to write the one step transition probability from state i to state j as

$$\begin{aligned} p_{ij}(dt) &= P[X(t+dt)=j|X(t)=i] \\ &= \alpha_{ij} dt + o(dt), \end{aligned} \quad (17)$$

where $\lim_{dt \rightarrow 0} \frac{o(dt)}{dt} = 0$.

The parameter α_{ij} is the transition rate from state i to state j . Since α_{ij} is constant, the time T_{ij} that the system stays in state i before making a transition to state j is exponentially distributed with parameter α_{ij} .

A transition probability matrix can be introduced

$$\underline{\underline{A}} = \begin{pmatrix} 1 - dt \sum_{j=1}^N \alpha_{0j} & \alpha_{01} dt & \dots & \alpha_{0N} dt \\ \alpha_{10} dt & 1 - dt \sum_{\substack{j=0 \\ j \neq 1}}^N \alpha_{1j} & \dots & \alpha_{1N} dt \\ \dots & \dots & \dots & \dots \end{pmatrix}, \quad (18)$$

so that the following matrix equation governing the Markov process can be written as

$$\underline{P}(t+dt) = \underline{P}(t) \underline{\underline{A}}, \quad (19)$$

where, for example, the first equation is

$$\begin{aligned} P_0(t+dt) &= \left[1 - dt \sum_{j=1}^N \alpha_{0j} \right] P_0(t) \\ &\quad + \alpha_{10} P_1(t) dt + \dots + \alpha_{N0} P_N(t) dt. \end{aligned} \quad (20)$$

Subtracting $P_0(t)$ on both sides, dividing by dt and in the limit of $dt \rightarrow 0$, one gets:

$$\begin{aligned} \frac{dP_0}{dt} = & - \sum_{j=1}^N \alpha_{0j} P_0(t) \\ & + \alpha_{10} P_1(t) + \dots + \alpha_{N0} P_N(t). \end{aligned} \quad (21)$$

Manipulating in the same way the other equations of the system (Eq. 19), one can write

$$\begin{aligned} \frac{d\underline{P}}{dt} &= \underline{P}(t) \underline{A}^*, \underline{A}^* \\ &= \begin{pmatrix} -\sum_{j=1}^N \alpha_{0j} & \alpha_{01} & \dots & \alpha_{0N} \\ \alpha_{10} & -\sum_{\substack{j=0 \\ j \neq 1}}^N \alpha_{1j} & \dots & \alpha_{1N} \\ \dots & \dots & \dots & \dots \end{pmatrix}. \end{aligned} \quad (22)$$

The above is a system of linear, first-order differential equations in the unknown state probabilities $P_j(t)$, $j = 0, 1, 2, \dots, N$, $t \geq 0$. The matrix $\underline{A}^*$ contains the transition rates of the system; to simplify the notation, from now on the transition rate matrix $\underline{A}^*$ will be simply denoted as $\underline{A}$. Note that $\alpha_{ii} = -\sum_{\substack{j=0 \\ j \neq i}}^N \alpha_{ij}$.

The system of equations (Eq. 22) is to be solved starting from the initial condition $\underline{P}(0) = \underline{C}$ representing probabilities of the initial states of the system units at $t = 0$. The easiest method of solution is again by Laplace transform. The Laplace transform of the state probability $P_j(t)$, $j = 0, 1, 2, \dots, N$, denoted by $\tilde{P}_j(s)$, is defined as $\tilde{P}_j(s) = L[P_j(t)] = \int_0^\infty e^{-st} P_j(t) dt$; correspondingly, the Laplace transform of the time derivative of $P_j(t)$ is

$$L\left(\frac{dP_j(t)}{dt}\right) = s \tilde{P}_j(s) - P_j(0), \quad j = 0, 1, \dots, N.$$

Laplace-transforming the fundamental equation of the Markov process (Eq. 22):

$$s \tilde{\underline{P}}(s) - \underline{C} = \tilde{\underline{P}}(s) \underline{A} \quad (23)$$

Figure 1. Markov diagram of a binary unit.

from which

$$\tilde{\underline{P}}(s) = \underline{C} [s\underline{I} - \underline{A}]^{-1}, \quad (24)$$

where $\underline{I}$ is the identity matrix. Then, applying the inverse Laplace transformation one may retrieve the state probabilities vector $\underline{P}(t)$.

Furthermore, the steady state probability vector $\underline{\Pi}$ of the system states can be found by simply setting to zero the derivative of $\underline{P}$ in the fundamental equation (Eq. 22):

$$\underline{\Pi} \underline{A} = 0. \quad (25)$$

Taking into account that $\sum_{j=0}^N \Pi_j = 1$, the steady state probabilities are found to be

$$\Pi_j = \frac{D_j}{\sum_{i=0}^N D_i} \quad j = 0, 1, 2, \dots, N, \quad (26)$$

where D_j is the determinant of the square matrix obtained from $\underline{A}$ by deleting the j th row and column.

Consider, for example, the simple case of a unit that can be in only two states, working (0) and failed (1). Let λ and μ be the rates of failure (transitions from state 0 to state 1) and repair (transitions from state 1 to state 0), respectively. The Markov diagram is given by Fig. 1 and the transition matrix takes the form

$$\underline{A} = \begin{pmatrix} -\lambda & \lambda \\ \mu & -\mu \end{pmatrix}.$$

The unit is assumed to be in operation at time $t = 0$, that is, $\underline{C} = [1, 0]$. To compute the transient behavior of the state probability vector from Equation (24), one first computes

the inverse matrix $(s\underline{I} - \underline{A})^{-1}$:

$$\begin{aligned} (s\underline{I} - \underline{A})^{-1} &= \begin{pmatrix} s + \lambda & -\lambda \\ -\mu & s + \mu \end{pmatrix}^{-1} \\ &= \frac{1}{\det[(s\underline{I} - \underline{A})^{-1}]} \begin{pmatrix} s + \lambda & \lambda \\ \mu & s + \mu \end{pmatrix} \\ &= \frac{1}{s^2 + \lambda s + \mu s} \begin{pmatrix} s + \lambda & \lambda \\ \mu & s + \mu \end{pmatrix}. \end{aligned}$$

from which

$$\tilde{P}(s) = \begin{pmatrix} \frac{s + \lambda}{s(s + \lambda + \mu)} & \frac{\lambda}{s(s + \lambda + \mu)} \end{pmatrix}.$$

The roots of the denominator are 0 and $-(\lambda + \mu)$ and applying the inverse Laplace transformation, the state probability vector in the time domain becomes

$$\begin{aligned} \underline{P}(t) &= \begin{pmatrix} \frac{\mu}{\lambda + \mu} + \frac{\lambda}{\lambda + \mu} e^{-(\lambda + \mu)t} \\ \frac{\lambda}{\lambda + \mu} - \frac{\lambda}{\lambda + \mu} e^{-(\lambda + \mu)t} \end{pmatrix}, \end{aligned}$$

where

$$P_0(t) = \frac{\mu}{\lambda + \mu} + \frac{\mu}{\lambda + \mu} e^{-(\lambda + \mu)t}$$

is the system instantaneous availability at time t , as found in Equation (4),

$$P_1(t) = \frac{\lambda}{\lambda + \mu} - \frac{\lambda}{\lambda + \mu} e^{-(\lambda + \mu)t}$$

is the system instantaneous unavailability at time t .

The system steady state probabilities are readily found to be

$$\begin{aligned} \Pi_0 &= \frac{\mu}{\lambda + \mu} \text{ (as in Eq. 3.)} \\ \Pi_1 &= \frac{\lambda}{\lambda + \mu}. \end{aligned}$$

In more complex cases, a system will have many states, some of which correspond to the system functioning according to the required specifications, whereas others represent configurations in which the system fails to perform its function. Letting S denote the subset of states in which the system is functioning

and F the subset of failed states, the system instantaneous availability at time t is computed by simply summing the probabilities of being in a success state at time t , that is,

$$p(t) = \sum_{i \in S} P_i(t) = 1 - q(t) = 1 - \sum_{j \in F} P_j(t). \quad (27)$$

AVAILABILITY OF COMPLEX SYSTEMS: MONTE CARLO SIMULATION

In realistic conditions, the behavior of a system may not respect the Markov property. In these cases, the analysis of the system availability may be effectively carried out by Monte Carlo simulation, which corresponds to performing a virtual experiment in which a large number of identical systems, each one behaving differently due to the stochastic character of the system behavior, are run for test during a given time and their failure occurrences are recorded [13,14] (see also the section titled “Simulation Model Building” in this encyclopedia). This, in principle, is the same procedure adopted in the reliability tests performed on individual units to estimate their failure rates, mean times to failure, or other parameters characteristic of their failure behavior (see also the section titled “Reliability Estimation and Testing” in this encyclopedia); the difference is that for units the tests can be actually done physically in laboratory, at reasonable costs and within reasonable testing times (possibly by resorting to accelerated testing techniques, when necessary; see also **Estimating Intensity and Mean Value Function**), whereas for systems, this is obviously impracticable due to the costs and times involved in systems failures. Thus, instead of making physical tests on a system, the stochastic process of transition among its states is modeled by defining the probabilistic distribution governing the transition process, and a large number of realizations are generated by sampling from it, the times and outcomes of the occurring transitions. Figure 2 shows a number of such realizations on the plane *system configuration* versus *time*: in such

Figure 2. Random walks in the system configuration versus time plane. System configuration 3 is circled as a fault configuration. The squares identify points of transition (t, k) ; the circle bullets identify fault states. The dashed lines identify realizations leading to system failure before the mission time T_M .

a plane, the realizations take the form of random walks made of straight segments parallel to the time axis in-between transitions, when the system is in a given configuration and vertical stochastic jumps to new system configurations at the stochastic times when transitions occur (see also the section titled “Diffusion Processes and Random Walks” in this encyclopedia).

For the purpose of reliability and availability analysis, a subset Γ of the system configurations is identified as the set of fault states. Whenever the system enters one such configuration, its failure is recorded together with its time of occurrence. With reference to a given time t of interest, an estimate of the probability of system failure before such time, that is of the unreliability at time t , can be obtained by the frequency of system failures before t , computed by dividing the number of random walk realizations that record a system failure before t by the total number of random walk realizations simulated.

For the availability analysis, let us consider a generic single realization and suppose that the system enters a failed state $k \in \Gamma$ at time τ_{in} , exiting from it at a next transition at time τ_{out} . The time is suitably discretized in intervals of length Δt and counters are introduced, which accumulate the unavailability contributions in the time channels: a unitary weight is accumulated in the counters for all

the time channels within $[\tau_{in}, \tau_{out}]$. At the end of the simulation of the random walks, the content of each counter divided by the time interval Δt and by the number of random walks simulated, and gives an estimate of the instantaneous unavailability at that counter time.

The Monte Carlo simulation of one single system random walk entails the repeated sampling from the probabilistic transport distribution of the time of occurrence of the next transition and of the new configuration reached by the system as outcome of the transition, starting from the current system configuration. This can be done in two ways, which give rise to the so-called *indirect* and *direct* Monte Carlo approaches [15].

Indirect Simulation Method

The indirect approach consists in sampling first, the time t of a system transition from the conditional probability density $T(t|t', k')$ of the system performing at time t one of its possible transitions out of k' entered at the previous transition at time t' . Then, the transition to the new configuration k actually occurring is sampled from the conditional probability $C(k|t, k')$ that the system enters the new state k given that a transition has occurred at t starting from the system in state k' . The procedure then repeats to the next transition.

Figure 3. A simple series-parallel logic.

Table 1. Transition rates for the components A, B and C of the system in Figure 3

Initial	Arrival		
	1	2	3
1	0	$\lambda_{1 \rightarrow 2}^{A(B)}$	$\lambda_{1 \rightarrow 3}^{A(B)}$
2	$\lambda_{2 \rightarrow 1}^{A(B)}$	0	$\lambda_{2 \rightarrow 3}^{A(B)}$
3	$\lambda_{3 \rightarrow 1}^{A(B)}$	$\lambda_{3 \rightarrow 2}^{A(B)}$	0

Initial	Arrival			
	1	2	3	4
1	0	$\lambda_{1 \rightarrow 2}^C$	$\lambda_{1 \rightarrow 3}^C$	$\lambda_{1 \rightarrow 4}^C$
2	$\lambda_{2 \rightarrow 1}^C$	0	$\lambda_{2 \rightarrow 3}^C$	$\lambda_{2 \rightarrow 4}^C$
3	$\lambda_{3 \rightarrow 1}^C$	$\lambda_{3 \rightarrow 2}^C$	0	$\lambda_{3 \rightarrow 4}^C$
4	$\lambda_{4 \rightarrow 1}^C$	$\lambda_{4 \rightarrow 2}^C$	$\lambda_{4 \rightarrow 3}^C$	0

Consider for example, the system in Fig. 3, consisting of units A and B in active parallel followed by unit C in series. Units A and B have two distinct modes of operation and a failure state, whereas unit C has three modes of operation and a failure state. For example, if A and B were pumps, the two modes of operation could represent the 50% and 100% flow modes; if C were a valve, the three modes of operation could represent the “fully open,” “half open,” and “closed” modes.

For simplicity of illustration, let us assume that the units’ times of transition between states are exponentially distributed and denoted by $\lambda_{j_i \rightarrow m_i}^i$, the rate of transition of unit i going from its state j_i to the state m_i . Table 1 gives the transition rates matrices in symbolic form for units A, B, and C of the example (with the rate of self-transition $\lambda_{j_i \rightarrow j_i}^i = 0$ by definition).

The units are initially ($t = 0$) in their nominal states, which are labeled with the index

1 (e.g., pumps A and B at 50% flow and valve C fully open), whereas the failure states are labeled with the index 3 for the units A and B and with the index 4 for unit C.

The logic of operation is such that there is one minimal cut set (failure configuration) of order 1, corresponding to unit C in state 4, and one minimal cut set (failure configuration) of order 2, corresponding to both units A and B being in their respective failed states 3.

Let us consider one random walk, starting at $t_0 = 0$ with all units in their nominal states ($j_A = 1, j_B = 1, j_C = 1$). The rate of transition of unit A(B) out of its nominal state 1 is simply

$$\lambda_1^{A(B)} = \lambda_{1 \rightarrow 2}^{A(B)} + \lambda_{1 \rightarrow 3}^{A(B)}, \quad (28)$$

since the transition times are exponentially distributed and states 2 and 3 are the mutually exclusive and exhaustive arrival states of the transition. Similarly, the transition rate of unit C out of its nominal state 1 is

$$\lambda_1^C = \lambda_{1 \rightarrow 2}^C + \lambda_{1 \rightarrow 3}^C + \lambda_{1 \rightarrow 4}^C. \quad (29)$$

It follows, then, that the rate of transition of the system out of its current configuration ($j_A = 1, j_B = 1, j_C = 1$) is

$$\lambda^{(1,1,1)} = \lambda_1^A + \lambda_1^B + \lambda_1^C. \quad (30)$$

The first system transition time t_1 is sampled by applying the inverse transform method for continuous distributions [15]

$$t_1 = t_0 - \frac{1}{\lambda^{(1,1,1)}} \ln(1 - R_t), \quad (31)$$

where

$$R_t \approx U[0, 1).$$

Assuming that $t_1 < T_M$, the system mission time, (otherwise one would proceed to simulate the successive system realization), one needs to determine which transition has occurred, that is, which unit has undergone the transition and to which arrival state. This can be done by resorting to the inverse transform method for discrete distributions [15]. The probabilities of units A, B, C undergoing a transition out of their initial nominal states

Figure 5. Pictorial representation of the sampling of the arrival state of the transition by the inverse transform method for discrete distributions.

1, given that a transition occurs at time t_1 , are

$$\frac{\lambda_1^A}{\lambda^{(1,1,1)}}, \quad \frac{\lambda_1^B}{\lambda^{(1,1,1)}}, \quad \frac{\lambda_1^C}{\lambda^{(1,1,1)}}, \quad (32)$$

respectively.

Figure 4 shows an example in which the sampled random number $R_C \approx U[0, 1]$ is such that unit B undergoes the transition.

Given that at t_1 unit B undergoes a transition, its arrival state can be sampled by applying again the inverse transform method for discrete distributions, this time, to the set of discrete probabilities $\left\{ \frac{\lambda_{1 \rightarrow 2}^B}{\lambda_1^B}, \frac{\lambda_{1 \rightarrow 3}^B}{\lambda_1^B} \right\}$ of the mutually exclusive and exhaustive arrival states of unit B, as shown in Fig. 5 in which the sampled random number $R_S \approx U[0, 1]$ is assumed to be such that unit B fails (state 3).

As a result of this first transition, at t_1 the system enters configuration (1,3,1). The simulation now continues with the sampling of the next transition time t_2 , based on the updated system transition rate

$$\lambda^{(1,3,1)} = \lambda_1^A + \lambda_3^B + \lambda_1^C. \quad (33)$$

The next transition, then, occurs at

$$t_2 = t_1 - \frac{1}{\lambda^{(1,3,1)}} \ln(1 - R_t), \quad (34)$$

where

$$R_t \approx U[0, 1).$$

Assuming again that $t_2 < T_M$, the unit undergoing the transition and its arrival

state are sampled as before by application of the inverse transform method to the appropriate discrete probabilities.

The trial simulation of the system random walk proceeds through the various transitions from one system configuration to another, until T_M .

As explained earlier, when the system enters a failed configuration $(*, *, 4)$ or $(3, 3, *)$, where the $*$ denotes any state of the unit, its occurrence is recorded. More specifically, from the point of view of the practical implementation into a computer code, the system mission time is subdivided in intervals of length Δt and to each time interval an *unreliability* counter $C^R(t)$ is associated to record the occurrence of a failure: at the time τ when the system enters a fault state, a 1 is collected into all the unreliability counters $C^R(t)$ associated with times t successive to the failure occurrence time, that is $t \in [\tau, T_M]$. After simulating a large number of random walk trials M , an estimate of the system unreliability can be obtained by simply dividing by M and by the time interval Δt , the accumulated contents of the counters $C^R(t)$, $t \in [0, T_M]$. Similarly, the estimation of the system unavailability is obtained by collecting a 1 in the *unavailability* counters $C^A(t)$ associated with all times t successive to the failure, up to the exit of the system from the failed configuration, that is, its repair. As previously explained, the estimate of the system instantaneous unavailability is obtained by dividing by M and by Δt ,

Figure 6. Direct simulation method. The squares identify unit transitions; the circle bullets identify fault states.

the accumulated contents of the counters $C^A(t)$, $t \in [0, T_M]$.

Direct Simulation Method

The direct Monte Carlo simulation method differs from the indirect one in that the system transitions are not sampled by considering the probability distribution governing the transport of the whole system, but rather by sampling directly the times of all possible transitions of all individual units of the system and then arranging the transitions along a timeline in increasing order, in accordance to their times of occurrence. The unit that actually performs the transition is the one corresponding to the first transition in the timeline.

The timeline is updated after each transition occurs, to include the new possible transitions that the transient unit can perform from its new state.

With respect to the previous example of Fig. 5, starting at $t = 0$ with the system in nominal configuration (1,1,1) one would sample the times of all the possible unit transitions (Fig. 6). The simulation then proceeds to the successive times in the list, in correspondence with which, a system transition occurs. After each transition, the timeline is updated by cancelling the times of the transitions relating to the unit, which has undergone the last transition and by inserting the

newly sampled times of the transitions of the same unit from its new state.

Again, when during the trial the system enters a fault configuration 1's are collected in the system unreliability and unavailability counters associated to the time intervals beyond that time, as with the indirect procedure explained above, and in the end, after M trials, the unreliability and unavailability estimates are computed.

Compared to the previous indirect method, the direct approach is more suitable for systems whose units' failure and repair behaviors are represented by different stochastic distribution laws.

On the other hand, it is important to point out that when dependences among units are present (e.g., due to share-load or stand-by configurations), the distribution of the next transition time of a unit may be affected by the transition undergone by another unit, in which case the next transition time of the affected unit (and not only of the transient unit) has also to be resampled after the transition. This can increase the burden, and thus reduce the performance of the direct simulation approach.

de l'Adour, Bâtiment IPRA,
Pau cedex France

This article presents stochastic models and associated tools for the availability assessment of a repairable system. Owing to the limited scope of the article, we concentrate on the classical continuous-time pointwise and asymptotic availabilities: we set $E = \mathcal{U} \cup \mathcal{D}$ with $\mathcal{U} \cap \mathcal{D} = \emptyset$, where $\mathcal{U}$ and $\mathcal{D}$ stand for the up- and down-state sets, respectively; the system state is described by a stochastic process $(X_t)_{t \geq 0}$ with $X_t \in E$, and the point availability and its asymptotic version are defined as

$$A(t) = \mathbb{P}(X_t \in \mathcal{U}) \text{ for } t \geq 0,$$

$$A(\infty) = \lim_{t \rightarrow +\infty} A(t).$$

Other notions of availability may be found in the literature, please see **Point and Interval Availability** and Ref. 1, with lots of references therein.

The article is divided into three sections. The section titled “Availability in Alternating Renewal Models” is devoted to two-state systems, which are considered to be either up or down, with no in-between states. In this case, the system is commonly modeled by a so-called alternating renewal process, which has been extensively studied in the reliability literature [2,3], see also **Alternating Renewal Processes**.

The section titled “Availability in Markov and Semi-Markov Models” deals with systems with finitely many possible states: typically, such systems are formed of components, which can be up or down, leading to more or less degraded up- and down-states. In such a context, the most commonly used

stochastic model is a jump Markov process with a finite state space, which has been thoroughly studied and broadly used in industry [4], see also the section titled “Continuous-time Markov Chains (CTMCs)” in this encyclopedia. Such a model implies that both failure and repair rates should remain constant. This drawback has led to the development and use of semi-Markov processes, which allow for a little more modeling flexibility [5,6]; see also **Semi-Markov Processes**. The section titled “Markov Models” deals with jump Markov processes and the section titled “Semi-Markov Models” with semi-Markov processes.

Finally, the section titled “Availability in Regenerative and Markov Regenerative Models” is devoted to more general systems, which present regenerative and Markov regenerative properties, with no restrictive condition on the state space or other: between (Markov) regeneration points, the system may have a very general behavior, see [7], **Regenerative Processes**, and **Markov Regenerative Processes** for details. As we shall see, the (Markov) regeneration property then allows to concentrate on the behavior of the system between (Markov) regeneration points, to derive both point and asymptotic availabilities.

In order to illustrate the different stochastic models and associated tools, a small and educational example is used all over the article, under various assumptions: a series system is considered, which is formed of two stochastically independent components A and B , with respective failure and repair rates $(\lambda_A(x), \mu_A(x))$ and $(\lambda_B(x), \mu_B(x))$. (The components’ repair durations and times to failure are hence assumed to admit a density with respect to Lebesgue measure). The system always starts from its perfect working state. Owing to its structure, the system is down as soon as one component is down. A repair immediately begins at the failure and puts a component back to its perfect working state (as good as new repairs). According to the cases, the failure of one component

(and hence of the system) may involve the suspension of the other or not, that is by failure of one component, the other one may go on aging and undertake failure or not, with an eventually reduced failure rate. In each case, both components may be entirely renewed (the repair is then said to be complete) or only the down component. Finally, the failure and repair rates may be constant or general, and the components identical or not.

A very good reference for a deeper insight on the models presented here and for other examples is Ref. 7; for the stochastic tools, see also Refs 5 and 8–10.

Throughout the article, if T stands for a generic random variable (r.v.), $\mathbb{P}_T$ stands for its distribution, $\mathbb{E}(T)$ for its expectation, $F_T(t) = \mathbb{P}(T \leq t)$ for its cumulative distribution function, and $\bar{F}_T(t) = \mathbb{P}(T > t) = 1 - F_T(t)$ for its survival function.

AVAILABILITY IN ALTERNATING RENEWAL MODELS

The Example

We assume both components to be identical with a common failure rate $\lambda(x)$ and a repair to be complete, with repair rate $\mu(x)$; we consequently assume that the repair duration always is the same, independent of the degradation state of the system. The length of an up-period is the minimum of two independent r.v.s with common rate $\lambda(x)$ and we have a succession of alternating up- and down independent periods, with respective associate rates $2\lambda(x)$ and $\mu(x)$. The behavior of the system may then be modeled by a so-called alternating renewal process.

The General Case

A system is considered, which evolves according to an alternating renewal process $(X_t)_{t \geq 0}$, where we set $X_t = 1$ when the system is up at time t and $X_t = 0$ when it is down. The system is assumed to start from its perfect working state at time $t = 0$. The successive up-periods are denoted by $U_1, \dots, U_n, \dots$ and the down ones by $V_1, \dots, V_n, \dots$. Setting $T_n = \sum_{i=1}^n (U_i + V_i)$ for $n \geq 1$, the points

$T_0 = 0, T_1, \dots, T_n, \dots$ appear as renewal points for the process $(X_t)_{t \geq 0}$. In order to avoid the trivial case $T_0 = T_1 = T_2 = \dots = 0$ almost surely and following Ref. 5, we assume that $\mathbb{P}(T_1 = 0) < 1$.

With this setting, the system point availability is

$$\begin{aligned} A(t) &= \mathbb{P}(X_t = 1) \\ &= \sum_{n=0}^{+\infty} \mathbb{P}(T_n \leq t < T_{n+1}) \end{aligned}$$

for all $t \geq 0$.

The main tool for its study is the renewal equation (1) fulfilled by $A(t)$, provided just later. To derive it, we classically separate the cases where the first renewal arrives after or before t and we get:

$$\begin{aligned} A(t) &= \mathbb{P}(X_t = 1; t < T_1) + \mathbb{P}(X_t = 1; t \geq T_1) \\ &= \mathbb{P}(t < U_1) \\ &\quad + \int_{[0,t]} \mathbb{P}(X_t = 1 | T_1 = u) \mathbb{P}_{T_1}(du). \end{aligned}$$

Using the regeneration property at time T_1 (see **Renewal Function and Renewal-Type Equations** or Ref. 2 for more details), we easily get

$$\begin{aligned} &\int_{[0,t]} \mathbb{P}(X_t = 1 | T_1 = u) \mathbb{P}_{T_1}(du) \\ &= \int_{[0,t]} A(t - u) \mathbb{P}_{T_1}(du) = (A * \mathbb{P}_{T_1})(t) \end{aligned}$$

and

$$A(t) = \bar{F}_{U_1}(t) + (A * \mathbb{P}_{T_1})(t), \quad (1)$$

where $\mathbb{P}_{T_1}(du) = (\mathbb{P}_{U_1+V_1})(du) = (\mathbb{P}_{U_1} * \mathbb{P}_{V_1})(du)$ and $*$ stands for the standard convolution.

Apart from very special cases (e.g., exponential distributions), the renewal equation (1) cannot be solved explicitly and numerical procedures have to be developed [11,12].

Limit theorems for solutions of renewal equations (see **Limit Theorems for Renewal Processes**) allow to get the asymptotic availability from Equation (1): setting $MUT = \mathbb{E}(U_1)$ to be the Mean Up Time of

the system on a cycle and $MDT = \mathbb{E}(V_1)$ to be its Mean Down Time, we get:

$$\begin{aligned} A(\infty) &= \frac{\int_0^{+\infty} \bar{F}_{U_1}(u) du}{\mathbb{E}(T_1)} \\ &= \frac{\mathbb{E}(U_1)}{\mathbb{E}(U_1) + \mathbb{E}(V_1)} \\ &= \frac{MUT}{MUT + MUT}, \end{aligned} \quad (2)$$

assuming $\mathbb{E}(U_1) + \mathbb{E}(V_1) < +\infty$ and the distribution of $T_1 = U_1 + V_1$ to be nonlattice [13].

Back to the Example

The times to failure of both components are here assumed to be gamma distributed $\Gamma(a_u, b_u)$, with the following p.d.f. (probability density function):

$$f_u(x) = \frac{1}{(b_u)^{a_u} \Gamma(a_u)} x^{a_u-1} e^{-x/b_u} \mathbf{1}_{\mathbb{R}_+}(x)$$

and parameters $(a_u, b_u) = (2, 1/3)$ (mean = $a_u b_u \simeq 0.6667$). The repairs also are gamma distributed with parameters $(a_d, b_d) = (3, 1/36)$ (mean = $a_d b_d \simeq 0.08333$). The point availability has been computed by discretization of Equation (1) and by Monte Carlo simulations. The results of both methods are plotted in Fig. 1, where MC stands for Monte Carlo simulation (5×10^4 histories), MC Sup

and MC Inf stand for the upper and lower bounds of the associated 95% confidence band and DM stands for the discretization method. (Similar notations are used all over the article). The asymptotic availability provided by (2) is also indicated in Fig. 1, with $A(\infty) \simeq 0.833$.

In most cases, a system may have several degraded up-states and/or several down-states and cannot hence be modeled by an alternating renewal process. The next section is devoted to such multistate systems, with Markovian or semi-Markovian degradation.

AVAILABILITY IN MARKOV AND SEMI-MARKOV MODELS

Markov Models

The Example: Case of Constant Failure and Repair Rates. We here come back to our example, in the case of different components with constant failure and repair rates ($\lambda_A(x) \equiv \bar{\lambda}_A$, $\mu_A(x) \equiv \bar{\mu}_A$, $\lambda_B(x) \equiv \bar{\lambda}_B$, $\mu_B(x) \equiv \bar{\mu}_B$). In case of failure of one component, the other one is suspended and cannot fail. The evolution of the system may then be modeled by a continuous-time Markov chain (CTMC) $(X_t)_{t \geq 0}$ with range in $E = \{(1, 1), (1, 0), (0, 1)\}$, where the first place refers to component A and the second one to component B, with an “1” indicating an up component, and an “0” a down one.

Figure 1. Point and asymptotic availabilities, case of an alternating renewal process.

Figure 2. The Markov graph in case of constant failure and repair rates.

The corresponding Markov graph is provided in Fig. 2.

The General Case. In the general case, a system is considered, which evolves in time according to a CTMC $(X_t)_{t \geq 0}$ with range in a finite state space E . We set $\mathcal{A}$ to be the generator matrix of $(X_t)_{t \geq 0}$ and $(P_t)_{t \geq 0}$ to be its transition semigroup:

$$P_t(i, j) = \mathbb{P}_i(X_t = j)$$

for all $i, j \in E$ and all $t \geq 0$, where $\mathbb{P}_i$ is the conditional distribution given that $X_0 = i$, see the section titled “Continuous-time Markov Chains (CTMCs)” in this encyclopedia for more details.

The point availability of the system starting from state i is

$$A_i(t) = \sum_{j \in \mathcal{U}} P_t(i, j) = \sum_{j \in \mathcal{U}} (e^{t\mathcal{A}})(i, j), \quad (3)$$

where $e^{t\mathcal{A}}$ refers to the matrix exponentiation.

In case $(X_t)_{t \geq 0}$ is irreducible (and hence recurrent, because of the finite state space), the CTMC $(X_t)_{t \geq 0}$ admits an unique stationary probability measure π , such that $\pi\mathcal{A} = 0$ and $\sum_{i \in E} \pi(i) = 1$, see **Asymptotic Behavior of Continuous-Time Markov Chains**. The asymptotic availability is then independent of the initial state with

$$A(\infty) = \sum_{i \in \mathcal{U}} \pi(i). \quad (4)$$

Back to the Example. Owing to the Markov graph provided in Fig. 2, the generator matrix of $(X_t)_{t \geq 0}$ is given by:

$$\mathcal{A} = \begin{pmatrix} -\bar{\lambda}_A - \bar{\lambda}_B & \bar{\lambda}_B & \bar{\lambda}_A \\ \bar{\mu}_B & -\bar{\mu}_B & 0 \\ \bar{\mu}_A & 0 & -\bar{\mu}_A \end{pmatrix}.$$

The point availability of the system is

$$\begin{aligned} A_{(1,1)}(t) &= \mathbb{P}_{(1,1)}(X_t = (1, 1)) \\ &= e^{t\mathcal{A}}((1, 1), (1, 1)). \end{aligned}$$

In case $\bar{\lambda}_A = \bar{\lambda}_B = \bar{\lambda}$ and $\bar{\mu}_A = \bar{\mu}_B = \bar{\mu}$, this easily provides

$$\begin{aligned} A_{(1,1)}(t) &= \frac{\bar{\mu}}{2\bar{\lambda} + \bar{\mu}} + \frac{2\bar{\lambda}}{2\bar{\lambda} + \bar{\mu}} e^{-(2\bar{\lambda} + \bar{\mu})t} \quad \text{and} \\ A(\infty) &= \frac{\bar{\mu}}{2\bar{\lambda} + \bar{\mu}}. \end{aligned}$$

In case of different rates for A and B , we get

$$A(\infty) = \frac{\mu_A \mu_B}{\lambda_A \mu_B + \lambda_B \mu_A + \mu_A \mu_B},$$

and an easy but cumbersome expression for $A_{(1,1)}(t)$, which we do not provide.

Both point and asymptotic availabilities are plotted in Fig. 3 for $\bar{\lambda}_A = 1$, $\bar{\lambda}_B = 2$, $\bar{\mu}_A = 10$ and $\bar{\mu}_B = 15$, with $A(\infty) \simeq 0.811$.

In the Markovian case, both point and asymptotic availabilities hence have an easy expression with respect to the CTMC transition probabilities and stationary probability measure, see Equations (3) and (4). Though the transition probabilities have an explicit expression with respect to the generator matrix (Eq. 3), their numerical evaluation

Figure 3. Point and asymptotic availabilities, Markov & semi-Markov cases.

however leads to real difficulties in case of large Markov systems, due to a rapid explosion of the size of the state space with the number of components of the system. This has lead to an extensive literature devoted to their numerical assessment (see *Computational Methods for CTMCs* or Refs 14 and 15)

Another drawback of the Markovian models is the underlying assumption of constant failure and repair rates. Such a restrictive assumption may be partially removed by semi-Markov processes, as shown in the next section.

Semi-Markov Models

The Example: Case of Constant Failure Rates and General Repair Rates. We consider here, the same example as in section titled “The Example: Case of Constant Failure and Repair Rates” except the fact that the repair rates are now general $[\mu_A(x) \text{ and } \mu_B(x)]$, while both failure rates remain constant ($\bar{\lambda}_A$ and $\bar{\lambda}_B$). Just as in section titled “The Example: Case of Constant Failure and Repair Rates”, no further failure is possible when the system is down.

The possible changes in the system state are due to

- the failure of one component (with the other one suspended in its up-state);

- the end of repair of one component (with the other component up).

It is then easy to see that at each transition time, the system forgets its past; indeed, as the failure rates are constant, the repair of one component (with the other one up) puts the system back to its perfect working state. This means that the system fulfills the Markov property each time its state changes and hence behaves according to a semi-Markov process $(X_t)_{t \geq 0}$ (see *Semi-Markov Processes*).

The General Case. In the general case, a system is considered, which evolves in time according to a semi-Markov process $(X_t)_{t \geq 0}$ with range in E (finite) and with semi-Markov transition kernel $(q(i, j, dt))_{i, j \in E}$: we recall that $q(i, j, dt) = \mathbb{P}_i(X_{T_1} = j, T_1 \in dt)$, where T_1 stands for the first jump time of the process $(X_t)_{t \geq 0}$ (see *Semi-Markov Processes* for details). Setting $T_0 = 0 \leq T_1 \leq T_2 \leq \dots$ to be the successive jump times of $(X_t)_{t \geq 0}$, we assume that $\mathbb{P}_i(T_0 = T_1 = T_2 = \dots = 0) = 0$ for all $i \in E$, which here again avoids trivialities.

The point availability of the semi-Markov system starting from state i is

$$A_i(t) = \mathbb{P}_i(X_t \in \mathcal{U}) = \sum_{j \in \mathcal{U}} \mathbb{P}_i(X_t = j)$$

for all $i \in E$. By separating the cases where the first jump arrives after or before t as in the case of an alternating renewal process, we get

$$\begin{aligned} A_i(t) &= \mathbb{P}_i(X_t \in \mathcal{U}, T_1 > t) + \mathbb{P}_i(X_t \in \mathcal{U}, T_1 \leq t) \\ &= \mathbf{1}_{\mathcal{U}}(i) \mathbb{P}_i(T_1 > t) \\ &\quad + \sum_{k \in E} \int_{[0,t]} \mathbb{P}_i(X_t \in \mathcal{U} | T_1 = u, X_{T_1} = k) \\ &\quad \times q(i, k, du) \end{aligned}$$

Applying the Markov property at time T_1 , we have

$$\begin{aligned} \mathbb{P}_i(X_t \in \mathcal{U} | T_1 = u, X_{T_1} = k) \\ = \mathbb{P}_k(X_{t-u} \in \mathcal{U}) = A_k(t-u) \end{aligned}$$

This provides

$$A_i(t) = \mathbf{1}_{\mathcal{U}}(i) \mathbb{P}_i(T_1 > t) + (A * q)(i, t), \quad (5)$$

where we set

$$(A * q)(i, t) = \sum_{k \in E} \int_{[0,t]} A_k(t-u) q(i, k, du). \quad (6)$$

Equation (5) for $i \in E$ and $t \geq 0$ are known as *Markov renewal equations*, which have no explicit solutions in the general case and have to be solved numerically (see **Limit Theorems for Markov Renewal Processes** and Refs 1 and 16).

In the case that the semi-Markov process $(X_t)_{t \geq 0}$ is irreducible and that the sojourn times are nonarithmetic with finite means, the process $(X_t)_{t \geq 0}$ admits a unique stationary probability measure π , which is known to be identical to the unique stationary probability measure of a CTMC $(Y_t)_{t \geq 0}$, which has the same transition matrix $(\mathbb{P}_i(X_{T_1} = j) = \mathbb{P}_i(Y_{T_1} = j))$ and same mean sojourn times $\mathbb{E}_i(T_1)$ as $(X_t)_{t \geq 0}$ (see Refs 5 and 8 for details). This implies that both asymptotic availabilities for the semi-Markov process $(X_t)_{t \geq 0}$ and for the Markov process $(Y_t)_{t \geq 0}$ are identical.

Back to the Example. The semi-Markovian kernel associated with $(X_t)_{t \geq 0}$ is

$$(q(i, j, dt))_{i, j \in E} = \begin{pmatrix} 0 & \bar{\lambda}_B e^{-(\bar{\lambda}_A + \bar{\lambda}_B)t} dt & \bar{\lambda}_A e^{-(\bar{\lambda}_A + \bar{\lambda}_B)t} dt \\ f_{\mu_B}(t) dt & 0 & 0 \\ f_{\mu_A}(t) dt & 0 & 0 \end{pmatrix},$$

where $f_{\mu_A}(t)$ and $f_{\mu_B}(t)$ stand for the respective p.d.f.s associated with r.v.s with respective hazard rates $\mu_A(t)$ and $\mu_B(t)$, where

$$f_{\mu_A}(t) = \mu_A(t) e^{-\int_0^t \mu_A(u) du},$$

for all $t \geq 0$ and a similar expression for $f_{\mu_B}(t)$, with $\mu_B(t)$ substituted to $\mu_A(t)$.

The Markov renewal equations may here be written as

$$A_{(1,0)}(t) = \int_0^t A_{(1,1)}(t-u) f_{\mu_B}(u) du, \quad (7)$$

$$A_{(0,1)}(t) = \int_0^t A_{(1,1)}(t-u) f_{\mu_A}(u) du, \quad (8)$$

$$\begin{aligned} A_{(1,1)}(t) &= e^{-(\bar{\lambda}_A + \bar{\lambda}_B)t} \\ &\quad + \int_0^t A_{(1,0)}(t-u) \bar{\lambda}_B e^{-(\bar{\lambda}_A + \bar{\lambda}_B)u} du \\ &\quad + \int_0^t A_{(0,1)}(t-u) \bar{\lambda}_A e^{-(\bar{\lambda}_A + \bar{\lambda}_B)u} du. \end{aligned} \quad (9)$$

Substituting (7) and (8) in (9) easily provides

$$\begin{aligned} A_{(1,1)}(t) &= e^{-(\bar{\lambda}_A + \bar{\lambda}_B)t} \\ &\quad + \int_0^t A_{(1,1)}(v) G(t-v) dv \end{aligned}$$

with

$$\begin{aligned} G(v) &= \int_0^v (\bar{\lambda}_B f_{\mu_B}(v-u) + \bar{\lambda}_A f_{\mu_A}(v-u)) \\ &\quad \times e^{-(\bar{\lambda}_A + \bar{\lambda}_B)u} du, \end{aligned}$$

which we solve by discretization. The results are provided in the same figure as for the Markovian case (Fig. 3), with the same constant failure rates $(\bar{\lambda}_A = 1, \bar{\lambda}_B = 2)$ and gamma repair rates $\Gamma(3, 1/30)$ and

$\Gamma(3.5, 1/52.5)$ with the same means as in the Markovian case from section titled “Back to the Example” in the section titled “Markov Models” (1/10 and 1/15, respectively). As expected, we can observe that the asymptotic availability is the same in both cases, with a slower convergence in the Markovian case.

In a semi-Markov model, the system forgets its past each time it changes state. In the example, assume that the failure rates are not constant any more. In that case, at the end of repair of the down component, the suspended one is not as good as new and it needs to be repaired for the system to be entirely renewed (and for the system to forget its past). If the duration of this repair is independent of the degradation level of the suspended component, the system still is semi-Markovian. However, under the more realistic assumption of a repair depending on the degradation level, this is not true any more. This shows a limitation of the modeling power of the semi-Markov processes. (A classical other limitation is that a parallel two-unit system formed of two independent semi-Markovian components is not semi-Markovian any more). We now come to regenerative and semiregenerative models, which allow for more flexibility.

AVAILABILITY IN REGENERATIVE AND MARKOV REGENERATIVE MODELS

Regenerative Models

The Example. We consider here the case of general failure and repair rates, with suspension of the up component in case of failure. At failure, the system is completely repaired. A single repairman is considered so that the repair durations of both components are added. The repair of one component now depends on its degradation level: for a down component, its repair rate is $\mu_A(x)$ or $\mu_B(x)$, as before. When a component has been functioning for a duration u , the repair rate to bring it back to its perfect working state is some $\tilde{\mu}_A(x, u)$ (or $\tilde{\mu}_B(x, u)$), where $\tilde{\mu}_A(x, u)$ is some decreasing function in u

with $\lim_{u \rightarrow +\infty} \tilde{\mu}_A(x, u) = \mu_A(x)$ (the same for $\tilde{\mu}_B(x, u)$).

Under the previous assumptions, the state $(1, 1)$ is a regenerative state in the sense that each time the system enters this state, it starts again in a similar way as from the beginning and forgets its past. The periods between two successive arrivals in state $(1, 1)$ are called *cycles* and the process $(X_t)_{t \geq 0}$ appears as a regenerative one (see **Regenerative Processes**).

The General Case. In the general case, a system is considered, which evolves in time according to a regenerative process $(X_t)_{t \geq 0}$, with $(T_n)_{n \in \mathbb{N}}$ as regeneration times. Following the definition of Çinlar [5], this means that $(T_n)_{n \in \mathbb{N}}$ are the points of a renewal process such that

1. the T_n 's are stopping times adapted to $(X_t)_{t \geq 0}$ (and $\mathbb{P}(T_1 = 0) < 1$);
2. at each T_n , the future process $(X_{t+T_n})_{t \geq 0}$ given the past up to T_n (namely given the σ -algebra generated by $\{X_u, u \leq T_n\}$), is identically distributed as $(X_t)_{t \geq 0}$.

See **Regenerative Processes** or Ref. 5 for more details. This means that at each T_n , a regenerative system starts again as from the beginning and forgets its past. The evolution of the system between two regeneration points may here be very general.

Using the regeneration property at time T_1 , the point availability satisfies the following renewal equation:

$$\begin{aligned} A(t) &= \mathbb{P}(X_t \in \mathcal{U}, T_1 > t) + \mathbb{P}(X_t \in \mathcal{U}, T_1 \leq t) \\ &= \mathbb{P}(X_t \in \mathcal{U}, T_1 > t) \\ &\quad + \int_{[0, t]} A(t-u) \mathbb{P}_{T_1}(du). \end{aligned} \quad (10)$$

Assuming the distribution of T_1 to be non-lattice and $\mathbb{E}(T_1) < +\infty$, we derive [5]:

$$\begin{aligned} A(\infty) &= \frac{\int_0^{+\infty} \mathbb{P}(X_t \in \mathcal{U}, T_1 > t) dt}{\mathbb{E}(T_1)} \\ &= \frac{\mathbb{E}\left(\int_0^{T_1} \mathbf{1}_{\mathcal{U}}(X_t) dt\right)}{\mathbb{E}(T_1)} = \frac{\text{MUT}}{\text{MUT} + \text{MDT}}, \end{aligned} \quad (11)$$

where MUT and MDT, are respectively, the cumulated Mean Up Time and Mean Down Time of the system on a cycle.

Back to the Example. We assume that both times to failure are gamma distributed with the same means as in section titled “Availability in Markov and Semi-Markov Models” (where the failure rates were constant), and we take $\Gamma(2, 1/2)$ and $\Gamma(2, 1/4)$. The repair durations in case of failure are identically distributed as in the semi-Markovian case: $\Gamma(a_{R_A}, b_{R_A})$ and $\Gamma(a_{R_B}, b_{R_B})$ with $(a_{R_A}, b_{R_A}) = (3, 1/30)$ and $(a_{R_B}, b_{R_B}) = (3.5, 1/52.5)$, and respective means $m_{R_A} = a_{R_A} b_{R_A}$ and $m_{R_B} = a_{R_B} b_{R_B}$. When component A has been functioning for u time units, its repair duration is gamma distributed: $\Gamma(a_{R_A}, b_{R_A}(1 - \frac{1}{1+u^\alpha}))$, with mean $m_{R_A}(1 - \frac{1}{1+u^\alpha})$, where we assume $\alpha = 1/8$. The distribution of the repair duration is similar for component B, with (a_{R_B}, b_{R_B}) substituted to (a_{R_A}, b_{R_A}) and the same α .

A cycle begins with an up-period of length $U_1 = \min(Z_{\lambda_A}, Z_{\lambda_B})$, where Z_v stands for an r.v. with hazard rate $v(t)$, and where Z_{λ_A} and Z_{λ_B} are independent. (Other natural conditions of independence will be assumed further on, which will not be detailed). Then comes a down-period with length

$$\begin{aligned} V_1 &= \left(Z_{\mu_A} + Z_{\mu_B}(\cdot, Z_{\lambda_A})\right) \mathbf{1}_{\{Z_{\lambda_A} < Z_{\lambda_B}\}} \\ &\quad + \left(Z_{\mu_B} + Z_{\mu_A}(\cdot, Z_{\lambda_B})\right) \mathbf{1}_{\{Z_{\lambda_A} \geq Z_{\lambda_B}\}}, \end{aligned}$$

where, given Z_{λ_A} , the distribution of $Z_{\mu_B}(\cdot, Z_{\lambda_A})$ is $\Gamma\left(a_{R_B}, b_{R_B}\left(1 - \frac{1}{1+(Z_{\lambda_A})^\alpha}\right)\right)$ with

mean

$$\mathbb{E}\left(Z_{\mu_B}(\cdot, Z_{\lambda_A}) | Z_{\lambda_A}\right) = m_{R_B} \left(1 - \frac{1}{1 + (Z_{\lambda_A})^\alpha}\right). \quad (12)$$

Similarly,

$$\mathbb{E}\left(Z_{\mu_A}(\cdot, Z_{\lambda_B}) | Z_{\lambda_B}\right) = m_{R_A} \left(1 - \frac{1}{1 + (Z_{\lambda_B})^\alpha}\right).$$

Note that though up- and down periods are alternating, their durations are not independent so that an alternating renewal process cannot model the system evolution.

We have

$$\begin{aligned} \mathbb{P}(X_t \in \mathcal{U}, T_1 > t) &= \mathbb{P}(U_1 > t) \\ &= \bar{F}_{\lambda_A}(t) \bar{F}_{\lambda_B}(t), \end{aligned}$$

and the relation $T_1 = U_1 + V_1$ then allows to get a discretized version of Equation (10), which we solve numerically. The results are plotted in Fig. 4, as well as those by Monte Carlo simulations.

The asymptotic availability is computed via (11), with

$$\begin{aligned} \text{MUT} &= \mathbb{E}(U_1) = \mathbb{E}(\min(Z_{\lambda_A}, Z_{\lambda_B})) \\ &= \int_0^{+\infty} \bar{F}_{\lambda_A}(t) \bar{F}_{\lambda_B}(t) dt \stackrel{\text{def}}{=} U_{AB} \end{aligned}$$

and $\text{MDT} = \mathbb{E}(V_1) = R_{AB} + R_{BA}$, where

$$\begin{aligned} R_{AB} &= \mathbb{E}\left(\left(Z_{\mu_A} + Z_{\mu_B}(\cdot, Z_{\lambda_A})\right) \mathbf{1}_{\{Z_{\lambda_A} < Z_{\lambda_B}\}}\right) \\ &= \mathbb{E}(Z_{\mu_A}) \mathbb{P}(Z_{\lambda_A} < Z_{\lambda_B}) \\ &\quad + \mathbb{E}\left(\mathbb{E}\left(Z_{\mu_B}(\cdot, Z_{\lambda_A}) \mathbf{1}_{\{Z_{\lambda_A} < Z_{\lambda_B}\}} | Z_{\lambda_A}\right)\right) \\ &= m_{R_A} \int_0^{+\infty} f_{\lambda_A}(u) \bar{F}_{\lambda_B}(u) du \\ &\quad + \mathbb{E}\left(\mathbb{E}\left(Z_{\mu_B}(\cdot, Z_{\lambda_A}) | Z_{\lambda_A}\right) \times \mathbb{E}\left(\mathbf{1}_{\{Z_{\lambda_A} < Z_{\lambda_B}\}} | Z_{\lambda_A}\right)\right) \end{aligned}$$

Figure 4. Point and asymptotic availabilities, regenerative case.

$$\begin{aligned}
 &= m_{R_A} \int_0^{+\infty} f_{\lambda_A}(u) \bar{F}_{\lambda_B}(u) du \\
 &\quad + \mathbb{E} \left(m_{R_B} \left(1 - \frac{1}{1 + (Z_{\lambda_A})^\alpha} \right) \bar{F}_{\lambda_B}(Z_{\lambda_A}) \right) \\
 &= \int_0^{+\infty} \left(m_{R_A} + m_{R_B} \left(1 - \frac{1}{1 + u^\alpha} \right) \right) \\
 &\quad \times f_{\lambda_A}(u) \bar{F}_{\lambda_B}(u) du
 \end{aligned} \tag{13}$$

using Equation (12) for (13). A similar expression is valid for R_{BA} and we finally have:

$$A(\infty) = \frac{U_{AB}}{U_{AB} + R_{AB} + R_{BA}}$$

where each quantity is now easily computable. This provides: $A(\infty) \simeq 0.776$.

As already mentioned, regenerative processes allow for a great flexibility as for the system behavior between regeneration points. However, the numerical assessment of the asymptotic availability requires the computation of both mean up time and mean down time on a cycle, which is not always that easy, even in rather simple cases. (As for the point availability, it is generally still more complicated). In some cases, the system may forget its past when entering several states and not only one single state, which may lead to a so-called Markov regenerative process. Though most of the Markov regenerative processes used in reliability also are

regenerative processes, the Markov regeneration property usually leads to different expressions for the point and/or asymptotic availabilities from those obtained with the simple regeneration property, which may be easier to compute. The discussion on Markov Regenerative models follows.

Markov Regenerative Models

The Example. We first come back to our example in a slightly modified version: both failure rates are constant ($\lambda_A(x) \equiv \bar{\lambda}_A$, $\lambda_B(x) \equiv \bar{\lambda}_B$), and the repair rates are general ($\mu_A(x)$ and $\mu_B(x)$) as in section titled “The Example: Case of Constant Failure Rates and General Repair Rates.” However, in case of failure of one component, the other one may now fail while the down component is repaired, at a lower rate however ($\bar{\lambda}'_A$ and $\bar{\lambda}'_B$ with $\bar{\lambda}'_A \leq \bar{\lambda}_A$ and $\bar{\lambda}'_B \leq \bar{\lambda}_B$). There is one single repairman and the repair of one component is completed up to its end, even in case of arrival of a new failure. To model it, we add two new states to our system: state $(0_R, 0)$ which means that component A is down under repair and that component B is down, waiting for a repair; the same for state $(0, 0_R)$.

Entrance in state $(1, 1)$ clearly is a regenerative point and $(X_t)_{t \geq 0}$ is a regenerative process. However, the mean length of a cycle, here, is a little complicated by the fact that lots of different scenarios are

possible, such as $(1, 1) \rightarrow (0, 1) \rightarrow (0_R, 0) \rightarrow (1, 0) \rightarrow (0, 0_R) \rightarrow (0, 1) \rightarrow \dots \rightarrow (1, 1)$. An alternative model is however possible, which leads to simpler computations; indeed, because of the constant failure rates, the system forgets its past each time it enters states $(1, 1)$, $(1, 0)$ and $(0, 1)$. Note that the system, however, does not fulfill the same property when entering states $(0_R, 0)$ and $(0, 0_R)$. In such cases, the repair of one component has indeed already begun, with a general repair rate. The process $(X_t)_{t \geq 0}$ is consequently not semi-Markovian. One can nevertheless consider a new process $(Y_t)_{t \geq 0}$ defined on a new state space $F = \{1, 2, 3\}$, which enters state 1, 2, and 3 each time $(X_t)_{t \geq 0}$ enters the states $(1, 1)$, $(1, 0)$, and $(0, 1)$, respectively. The possible transitions for $(X_t)_{t \geq 0}$ from state $(1, 1)$ are $(1, 1) \rightarrow (1, 0)$ and $(1, 1) \rightarrow (0, 1)$ with respective rates $\bar{\lambda}_B$

$$(q(i, j, dt))_{i, j \in F} = \begin{pmatrix} 0 & \bar{\lambda}_B e^{-(\bar{\lambda}_A + \bar{\lambda}_B)t} dt & \bar{\lambda}_A e^{-(\bar{\lambda}_A + \bar{\lambda}_B)t} dt \\ p_1 f_{\mu_B}(t) dt & 0 & (1 - p_1) f_{\mu_B}(t) dt \\ p_2 f_{\mu_A}(t) dt & (1 - p_2) f_{\mu_A}(t) dt & 0 \end{pmatrix},$$

where $p_2 = \mathbb{P}(Z_{\mu_A} \leq Z_{\bar{\lambda}_B})$, same notations, and where $f_{\mu_A}(t)$ and $f_{\mu_B}(t)$ have been defined in Subsection 2.2.3. Though the process $(Y_t)_{t \geq 0}$ does not fully describe the system evolution, (the process $(X_t)_{t \geq 0}$ may evolve while $(Y_t)_{t \geq 0}$ remains constant), the process $(X_t)_{t \geq 0}$ forgets its past at each jump of the semi-Markovian process $(Y_t)_{t \geq 0}$. This means that $(X_t)_{t \geq 0}$ is a Markov regenerative process, with $(Y_t)_{t \geq 0}$ as imbedded semi-Markov process (or $(T_n, Y_{T_n})_{n \in \mathbb{N}}$ as imbedded Markov renewal process, equivalently).

The General Case. In the general case, a system is considered, which evolves in time according to a Markov regenerative (or semiregenerative) process $(X_t)_{t \geq 0}$, with state space E . Following Ref. 5, this means that $t \rightarrow X_t(\omega)$ is right continuous and has left-hand limits for almost all ω and that there exists a Markov renewal process $(T_n, Y_n)_{n \in \mathbb{N}}$ on a state space F (here assumed finite) such that (i) the T_n 's are stopping times adapted to $(X_t)_{t \geq 0}$ [with $\mathbb{P}_i(T_0 = T_1 = T_2 = \dots = 0) = 0$ for all $i \in F$]; (ii) for each T_n , the r.v. Y_n is measurable with respect to the

and $\bar{\lambda}_A$. The possible transitions for $(Y_t)_{t \geq 0}$ from state 1 hence are $1 \rightarrow 2$ and $1 \rightarrow 3$ with the same respective rates, $\bar{\lambda}_B$ and $\bar{\lambda}_A$. From state $(1, 0)$, the process $(X_t)_{t \geq 0}$ may go back to state $(1, 1)$ with probability $p_1 = \mathbb{P}(Z_{\mu_B} \leq Z_{\bar{\lambda}_A})$, where $Z_{\bar{\lambda}_A}$ and Z_{μ_B} stand for independent r.v.s with respective hazard rates $\bar{\lambda}_A$ and $\mu_B(t)$. From state $(1, 0)$, the process $(X_t)_{t \geq 0}$ may also go to state $(0, 0_R)$ and next to state $(0, 1)$ with probability $1 - p_1$. This means that from state 2, the possible transitions for $(Y_t)_{t \geq 0}$ are $2 \rightarrow 1$ and $2 \rightarrow 3$, with respective probabilities p_1 and $1 - p_1$. Moreover, the time spent in state 2 by $(Y_t)_{t \geq 0}$ is some r.v. with hazard rate $\mu_B(t)$. A similar reasoning is valid for state $(0, 1)$ and proves that the process $(Y_t)_{t \geq 0}$ is semi-Markovian, with the following semi-Markovian kernel:

σ -algebra $\sigma(X_u, u \leq T_n)$ generated by the past up to T_n ; (iii) at each T_n , the future process $(X_{t+T_n})_{t \geq 0}$ given the past up to T_n (i.e., given $\sigma(X_u, u \leq T_n)$) is identically distributed on $\{Y_n = i\}$ as $(X_t)_{t \geq 0}$ given $\{Y_0 = i\}$ (see **Markov Regenerative Processes** for more details). In other words, this means that the future of a Markov regenerative process after T_n only depends on Y_n and that Y_n only depends on the past of the process up to T_n . As in the case of a regenerative process, the evolution of the system between two jumps of $(Y_n)_{n \in \mathbb{N}}$ may be very general.

Setting $(q(i, j, dt))_{i, j \in F}$ to be the semi-Markov kernel associated to $(T_n, Y_n)_{n \in \mathbb{N}}$ and using the Markov property at time T_1 , the point availability of the system given that $Y_0 = i$ fulfills the following Markov renewal equation:

$$\begin{aligned} A_i(t) &= \mathbb{P}_i(X_t \in \mathcal{U}, T_1 > t) + \mathbb{P}_i(X_t \in \mathcal{U}, T_1 \leq t) \\ &= \mathbb{P}_i(X_t \in \mathcal{U}, T_1 > t) \\ &\quad + \sum_{j \in E} \int_{[0, t]} \mathbb{P}_i(X_t \in \mathcal{U} | T_1 = u, Y_1 = j) \\ &\quad \times q(i, j, du) \end{aligned}$$

$$\begin{aligned}
 &= \mathbb{P}_i (X_t \in \mathcal{U}, T_1 > t) \\
 &\quad + \sum_{j \in E} \int_{[0, t]} A_j (t - u) q (i, j, du) \\
 &= \mathbb{P}_i (X_t \in \mathcal{U}, T_1 > t) + (A * q) (i, t), \quad (14)
 \end{aligned}$$

where $(A * q) (i, t)$ is defined in Equation (6).

Let us now suppose that the Markov renewal process $(T_n, Y_n)_{n \in \mathbb{N}}$ is irreducible with nonarithmetic sojourn times and means $m(i) = \mathbb{E}_i (T_1)$, and let π be the unique stationary probability measure of the Markov chain $(Y_n)_{n \in \mathbb{N}}$. The asymptotic availability $A(\infty)$ then exists and is [5]

$$\begin{aligned}
 A(\infty) &= \frac{\sum_{i \in F} \pi(i) \int_0^{+\infty} \mathbb{P}_i (X_t \in \mathcal{U}, T_1 > t) dt}{\sum_{i \in F} \pi(i) m(i)} \\
 &= \frac{\sum_{i \in F} \pi(i) \mathbb{E}_i \left(\int_0^{T_1} \mathbf{1}_{\mathcal{U}} (X_t) dt \right)}{\mathbb{E}_{\pi} (T_1)} \quad (15)
 \end{aligned}$$

where symbols i and π in $\mathbb{P}_i$, $\mathbb{E}_i$, and $\mathbb{E}_{\pi}$ here refer to the initial distribution of $(Y_n)_{n \in \mathbb{N}}$.

This means that the asymptotic availability is the quotient of the system mean up time between arrivals of $(T_n, Y_n)_{n \in \mathbb{N}}$ divided by the mean interarrival length of $(T_n, Y_n)_{n \in \mathbb{N}}$, when $(T_n, Y_n)_{n \in \mathbb{N}}$ is in its steady state.

Back to the Example. We take $\bar{\lambda}_A = 1$, $\bar{\lambda}_B = 2$ as failure rates, and $\Gamma(3.5, 1/52.5)$,

for the repair distributions, as in the semi-Markovian case. We also take $\bar{\lambda}'_A = 0.5$ and $\bar{\lambda}'_B = 1$.

The Markov renewal Equations (14) may here be written as

$$\begin{aligned}
 A_1(t) &= e^{-(\bar{\lambda}_A + \bar{\lambda}_B)t} + \int_0^t A_2(t-u) q(1, 2, du) \\
 &\quad + \int_0^t A_3(t-u) q(1, 3, du) \\
 &= e^{-(\bar{\lambda}_A + \bar{\lambda}_B)t} + \int_0^t (\bar{\lambda}_B A_2(t-u) \\
 &\quad + \bar{\lambda}_A A_3(t-u)) e^{-(\bar{\lambda}_A + \bar{\lambda}_B)u} du, \\
 A_2(t) &= \int_0^t A_1(t-u) q(2, 1, du) \\
 &\quad + \int_0^t A_3(t-u) q(2, 3, du) \\
 &= \int_0^t (p_1 A_1(t-u) \\
 &\quad + (1-p_1) A_2(t-u)) f_{\mu_B}(u) du,
 \end{aligned}$$

with

$$\begin{aligned}
 p_1 &= \mathbb{P}(Z_{\mu_B} \leq Z_{\bar{\lambda}'_A}) = \int_0^{+\infty} f_{\mu_B}(t) e^{-\bar{\lambda}'_A t} dt \\
 &= \frac{1}{(1 + b_{R_B} \bar{\lambda}'_A)^{a_{R_B}}},
 \end{aligned}$$

and a similar equation for $A_2(t)$.

Figure 5. Point and asymptotic availabilities, Markov regenerative case.

This provides a set of three equations, which we discretize for their numerical resolution. Monte Carlo simulations are also performed. The results for $A_{(1,1)}(t)$ ($= A_1(t)$) are provided by both methods in Fig. 5, as well as the asymptotic availability, easily provided by Equation (15) with $A(\infty) \simeq 0.802$.

DISCUSSION AND FURTHER READING

In conclusion, we have presented here, classical stochastic models with (Markov) regenerative properties. For such models, the point availability has been proved to satisfy (Markov) renewal equations. The solving of such equations has, however, been seen to be generally impossible in full form and requires numerical procedures. We have here made the choice to use discretization techniques, which are easy to implement. Also, they can provide upper and lower bounds for the solutions. The results have been checked through Monte Carlo simulations, which are commonly used by practitioners in the reliability field, with generally longer computing times, however. Another numerical method might have been to use Laplace transforms, which are available in full form for the quantities of interest. The great progress made in their inversion in the last decade makes this method very appealing. Numerical difficulties may however arise in case of small or big arguments. Also, the precision of the results is not always available. See Ref. 17 for more details and references on the subject.

As for the asymptotic availability, it is usually simpler to compute than the point availability: it typically requires to evaluate the mean cycle duration and the mean up time on a cycle in the regenerative case, or similar quantities linked to the underlying Markov renewal process in the Markov regenerative case.

The classical models presented here actually sometimes (often?) appear as restrictive in the applications and even very simple systems may not meet with their assumptions: as an example, let us come back to

our two-unit series system, where one component is suspended when the other is down, with general repair and failure rates and only down components repaired. In that case, the system never forgets its past so that the system meets with none of the previous models. Monte Carlo simulations may however be performed, to compute both point and asymptotic availabilities. Another possibility is to use new models coming from dynamic reliability [18], which are presently arriving in “classical” reliability. Such models are called *piecewise deterministic Markov processes* [19] and have been proved to have a great modeling power [20]. Like the models presented here, their numerical assessment may be done by Monte Carlo simulations or by discretization methods [21,22].

Another drawback of the models presented here is that no aging is taken into account in the sense that at (Markov) regeneration points, the future evolution of the system given its present state is a stochastic replica of the past given the same starting state, without any evolution. Other possible models, which take aging into account are geometric processes, where up and down periods alternate with geometrically decreasing and increasing durations [23], nonhomogeneous Markov and semi-Markov processes with finite state spaces [24], or nonhomogeneous piecewise deterministic Markov processes [25].

AVERAGE REWARD OF A GIVEN MDP POLICY

MATTHEW D. BAILEY
School of Management, Bucknell
University, Lewisburg,
Pennsylvania

A Markov decision process (MDP) is a general model for formulating problems that involve a sequence of decisions made under uncertainty to optimize a given performance criterion (e.g., the minimization of costs or the maximization of profits). The sequential nature of the problem allows for the defining of stages or decision epochs. This allows for the separation of the class of MDPs into finite- and infinite-horizon problems. In finite-horizon problems, rewards are received over a finite number of stages whereas infinite horizon problems allow for the indefinite accumulation of rewards. Following the notation of Puterman [1], let S be the defined state space of the MDP. For every state $s \in S$, let the set of feasible decisions or actions be A_s , where for every action $a \in A_s$ the decision maker receives reward $r(s, a)$, where $|r(s, a)| \leq M < \infty$. A transition from state s to state j when action $a \in A_s$ is chosen occurs with probability $p(j | s, a)$. Let a stationary policy $\mu = \{d, d, \dots\}$ be a sequence of identical decision rules, where a decision rule d is a function mapping actions to states such that $d(s) \in A_s$. Such policies are called *stationary Markov deterministic policies*. The application of such a policy induces a discrete-time Markov chain (DTMC) with rewards (a Markov reward process) where X_t is the state of the system at transition t and Y_t is the action chosen at state X_t , so that $Y_t = d(X_t)$ (also refer to **Definition and Examples of DTMCs** and **DTMCs with Costs and Rewards**). The objective of an average reward MDP is to find a policy that maximizes the average expected reward per stage defined as the

gain:

$$g^\mu(s) = \lim_{N \rightarrow \infty} \frac{1}{N} E_s^\mu \left\{ \sum_{t=1}^N r(X_t, Y_t) \right\}, \quad (1)$$

where $E_s^\mu \{\}$ is the expected value under policy μ given the initial state s .

In contrast to discounted reward MDPs, the underlying structure of the DTMC induced by a feasible policy has an impact on the optimal policy for an average reward MDP. As a result, for a given policy, we must classify the underlying DTMC to determine the average reward of the policy. We review the situation where the state space is finite; a discussion of the infinite-state case can be found in Ref. 2. The induced DTMC may be classified as either unichain (a single recurrent communicating class and a potentially empty set of transient states) or multichain (more than one communicating class). In general, a unichain MDP requires that all deterministic stationary policies induce a unichain DTMC. In the case of a finite-state unichain DTMC, it follows from standard DTMC results that all of the recurrent states must be positive recurrent, that is independent of the beginning state; all recurrent states will be visited infinitely often and the expected number of epochs between visits to recurrent states is finite (refer **Definition and Examples of DTMCs**). As a result, the average expected reward of such a system is independent of the beginning state (the gain is constant) and determined by the frequency of visits to each state. Therefore, it can be shown that for any state $i \in S$,

$$g^\mu(i) = \sum_{s \in S} \pi_{(s, d(s))} r(s, d(s)), \quad (2)$$

where $\pi_{(s, d(s))}$ is the long-run fraction of the transitions the DTMC spends in state s under decision rule d . From the theory of DTMCs, these values can be found as the

unique solution to

$$\begin{aligned}\pi_{(j,d(j))} &= \sum_{s \in S} \pi_{(s,d(s))} p(j | s, d(s)), \\ \sum_{s \in S} \pi_{(s,d(s))} &= 1, \\ \pi_{(s,d(s))} &\geq 0.\end{aligned}\quad (3)$$

As seen above, the gain of a policy is defined by the steady-state behavior of the system. In addition, the average rewards received before the system is in steady state can be of interest when comparing policies and utilizing more computationally efficient methods for determining the gain of a policy. To this end, we present the bias, h beginning in state s for a fixed policy to be

$$h^\mu(s) = \lim_{N \rightarrow \infty} \frac{1}{N} \sum_{k=1}^N E_s^\mu \left\{ \sum_{t=1}^k [r(X_t) - g(X_t)] \right\}, \quad (4)$$

which for an aperiodic DTMC may be simplified to

$$h^\mu(s) = \sum_{k=1}^{\infty} E_s^\mu \{r(X_t) - g(X_t)\}. \quad (5)$$

By the definition of the gain above, when the system reaches steady state the contribution to the bias will be zero. However, while the system is transient the bias will record the average expected deviation from the gain. While two policies may have identical gain, they may differ considerably in bias due to the transient behavior and reward structure of the system (called *bias optimality* [3]). Similar to the gain, the bias for a policy can be determined from the limiting matrix P^* , where

$$P^* = \lim_{N \rightarrow \infty} \frac{1}{N} \sum_{t=1}^N P^{t-1}, \quad (6)$$

and P^{t-1} is the $(t-1)$ -step transition probability matrix of the underlying DTMC. The rows of the limiting matrix are identical and the components are given by the $\pi_{(s,d(s))}$ values found from the previous set of

equations. Given P^* , the vector of biases h , can be found by

$$h = (I - P + P^*)^{-1}(I - P^*)r, \quad (7)$$

where r is the vector of rewards for the policy μ and $(I - P + P^*)^{-1}(I - P^*)$ is called the *Drazin inverse* of $(I - P)$.

Example. Let $S = \{s_1, s_2\}$ with stationary policy μ comprise decision rule d , where

$$\begin{aligned}p(s_1 | s_1, d(s_1)) &= 0, \\ p(s_2 | s_1, d(s_1)) &= 1, \\ p(s_1 | s_2, d(s_2)) &= 1/2, \\ p(s_2 | s_2, d(s_2)) &= 1/2,\end{aligned}$$

and

$$r(s_1, d(s_1)) = -2 \quad r(s_2, d(s_2)) = 1.$$

By definition,

$$P = \begin{bmatrix} 0 & 1 \\ 1/2 & 1/2 \end{bmatrix}$$

and

$$r = \begin{bmatrix} -2 \\ 1 \end{bmatrix}.$$

It can be easily shown that

$$P^* = \begin{bmatrix} 1/3 & 2/3 \\ 1/3 & 2/3 \end{bmatrix}$$

and using Equation (2) we can compute

$$g = [1/3 \quad 2/3] \begin{bmatrix} -2 \\ 1 \end{bmatrix} = \begin{bmatrix} 0 \\ 0 \end{bmatrix}.$$

Finally, from Equation (7)

$$h = \begin{bmatrix} 4/9 & -4/9 \\ -2/9 & 2/9 \end{bmatrix} \begin{bmatrix} -2 \\ 1 \end{bmatrix} = \begin{bmatrix} -4/3 \\ 2/3 \end{bmatrix}.$$

However, the above methodology for determining the bias is typically not computationally efficient. When our underlying DTMC is

unichain, the average reward can be determined as the unique solution to

$$r - g + (P - I)h = 0, \quad (8)$$

where g is the unknown vector of gains (each component of the vector is identical by Equation 2). While the gain can be uniquely determined from Equation (8), the vector h is the bias vector if $P^*h = 0$.

In the instance where a fixed policy induces a multichain DTMC, we can use an approach similar to that given above. For each closed irreducible recurrent class, say $R_1, R_2, R_3, \dots, R_m$ the gain will be constant for any state in the same class. If we view each class as an individual unichain DTMC, we can determine the gain for that recurrent class as above. In the case of a state in a transient class T , the gain will be determined by which recurrent class the system eventually enters. Once the gain for the states in the recurrent classes have been determined and by conditioning on the first transition from the transient state, the gains for transient states can be determined by solving the set of equations

$$\begin{aligned} g(s) = & \sum_{k \in R_1 \cup R_2 \dots R_m} p(k | s, d(s))g(k) \\ & + \sum_{j \in T} p(j | s, d(s))g(j) \quad \forall s \in T. \end{aligned} \quad (9)$$

For a more in-depth discussion on determining the average reward for a given MDP policy, we refer the reader to Refs 1, 3, and 4.

AVIATION SAFETY AND SECURITY

ARNOLD BARNETT
Sloan School of Management,
Operations Research Center
Massachusetts Institute of
Technology, Cambridge,
Massachusetts

Aviation safety and security is a very broad domain, which extends well beyond the contours of operations research and management science (OR/MS). But OR/MS can contribute in this area to two key respects: quantifying the risks that safety and security threats pose to air travelers, and suggesting which measures to reduce aviation risk are most likely to be beneficial. In this brief introductory essay, we offer some illustrations of these points. We restrict our focus on passenger air travel and, in the interests of brevity, limit the discussion to scheduled jet travel.

HOW SAFE?

Surveys suggest that, at one point or another, most air travelers are nervous about their safety in flight. But how dangerous is it to fly? To put the question more pointedly and specifically, what is the chance of being killed during an air journey? We begin with the risks posed by aviation accidents, and turn later to the threats posed by terrorists and other saboteurs.

Finding the appropriate metric for the mortality risk of air travel is not straightforward, as is suggested by considering some of the metrics now in common use. One statistic—used by the US National Transportation Safety Board, among others—is *fatal accidents per million flight hours*. Unfortunately, both the numerator and the denominator of the ratio are problematic. The term “fatal accident” obliterates the distinction between a crash that kills 1 person out of 200 on board and another that kills 200 out of 200. And the measure

gives no weight to safety improvements (e.g., fire-retardant materials) that reduce fatalities but do not prevent them. Moreover, the emphasis on hours flown misses the point that the heavy majority of fatal accidents occurs in the takeoff/climb or descent/landing phases of flight. Boeing reports that, over the period 1998–2007, only 10% of worldwide jet accidents that caused on-board fatalities occurred during the cruise phase of flight [1]. In consequence, the number of flights performed, rather than their durations, is a better guide to exposure to risk.

Another statistic that has long been used is *hull losses per 100,000 flight departures*. A hull loss is an accident that damages the plane beyond repair (the aerial equivalent of “totaling” a car.) In focusing on flight departures rather than on flight hours, this ratio recognizes that the distance or duration of the flight bears scant relationship to its accident risk. If, however, the aim is to gauge passenger death risk, then hull loss is a questionable proxy, because the passenger survival rate in hull losses ranges from 0% to 100%. There have been many instances in which a plane landed with major damage but, because of well-executed emergency procedures, all passengers were evacuated before the plane was engulfed in flames and became a hull loss. If such rescues are becoming more common, then a mere count of hull losses would fail to reflect that salient point.

Yet another statistic of interest is the ratio of *passengers killed to passengers carried*. This indicator has a plausible connection to the chance that a current passenger will be killed, for it literally reports what fraction of passengers were killed in a recent period. But weighting a crash by the number of fatalities can create difficulties. If a jetliner hits a mountain killing all passengers aboard, the implications about air safety are not twice as great if the plane is full rather than one-half full. And 22 deaths out of 22 aboard does not mean the same thing as 22 deaths out of 220 aboard (In the latter case, an excellent crew response may have saved 90% of

the passengers). In other words, risk statistics that use deaths in the numerator are vulnerable to meaningless fluctuations in the proportion of seats occupied, yet insensitive to large differences in the fraction of passengers who survived the crash.

Beyond the three indicators just discussed, there are several others that also seem questionable as guides to airplane mortality risk [2]. Applying operations research reasoning, this author has come up with an alternative measure that, while not perfect, may avoid the shortcomings just mentioned.

THE Q-STATISTIC

The Q-statistic is the answer to the question:

Suppose that a person chose a flight *completely at random* from among the set of interest (e.g., scheduled British domestic jet flights in the 1990s). What is the probability that she would not survive the flight?

The Q-statistic—which is essentially death risk per flight—assumes that there are N flights which can be indexed as $(1, 2, 3 \dots, N)$. We define x_i as the fraction of passengers on flight i who do not survive it (For example, if the flight lands safely, then $x_i = 0$; if it crashes and 20% of the passengers perish, then $x_i = 0.2$).

A formula for the Q-statistic arises if we note that each of the N flights has the same chance of $1/N$ of being selected at random and that, if flight i was selected, the traveler's conditional death risk is x_i . One way of dying because of the "flight lottery" would be to choose flight 1 at random and then to perish; the probability of this event is $(1/N)x_1$. The overall chance of dying would be the sum of the probabilities of all the N mutually exclusive ways that a fatal outcome can arise. In consequence, Q follows the rule:

$$Q = (1/N)x_1 + (1/N)x_2 + \dots (1/N)x_N \\ = \sum x_i \div N \quad (1)$$

Under this formula, the Q-statistic avoids several difficulties of the metrics previously discussed:

- The statistic weights each crash by the *fraction* of passengers killed. Thus,

a crash into a mountain that killed everyone on the plane would be treated the same way regardless of how many people happened to be on board that day. And a high survival rate in a crash would be treated very differently from a low survival rate.

- In accordance with empirical evidence, the calculation gives no weight of the mileage or duration of the flight.
- The calculation of Q is surprisingly easy. N is generally known from publicly available data. The conditional probability x_i is almost always zero and, when it is not, official reports about the crash make clear the value of x_i .
- The intuitive interpretation of Q is straightforward. While Q can only be calculated for a period that has ended, a recent Q-value is a strong approximation of the chance of dying on a flight today.

A disadvantage of the Q-statistic is that it does not reflect differences in risk among the flights within the set of interest. Flights in certain weather conditions or using certain types of aircraft might entail higher risk than others, meaning that death risk for a particular flight can differ from the overall Q-value (Of course, one could calculate Q-statistic by aircraft type if that seems desirable, and could at least approximate death risk per flight in adverse weather).

Some Calculated Q-Values

Table 1 below presents *accidental* death risk per flight for scheduled jet operations for various decades since 1960, which was essentially the start of the jet age (We will turn later to death risk caused by criminal and terrorist acts). The flights are divided into two categories based on the national origins of the airlines that performed them: *First-World* airlines are defined as those from the United States, Southern and Western Europe, the former British Commonwealth (Canada, Australia, and New Zealand), and Japan and Israel from Asia. All other flights are operated by *Developing-World* airlines.

Table 1. Accidental Death Risk per Flight, 1960–2008, for Different Decades and Two Groups of Jet Airlines

Period	Death Risk per Flight (Q-Statistic)
First-World airlines	
1960–1969	1 in 1 million
1970–1979	1 in 2 million
1980–1989	1 in 4 million
1990–1999	1 in 8 million
2000–2008	1 in 20 million
Developing-World airlines	
1960–1969	1 in 100,000
1970–1979	1 in 200,000
1980–1989	1 in 400,000
1990–1999	1 in 500,000
2000–2008	1 in 2 million

Notes: These statistics do not include crashes caused by criminal or terrorist acts. The calculations entail some approximations about the numbers of flights performed; [3,4] for discussions of the methodology and data sources used.

The key patterns in the data are obvious. Throughout the world and without any exceptions, jet travel has consistently become safer decade by decade. Passenger mortality risk fell by 95% between 1960–1969 and 2000–2008, at a surprisingly constant rate of about a factor of 2 per decade. It is also apparent that death risk is far lower on jet flights by First-World airlines than on those by Developing-World carriers. In every decade, the Q-statistic for the Developing-World was about a factor of 10 higher than the First-World statistic.

What does it mean intuitively to say that the accidental death risk per flight on a First-World jet carrier is now about 1 in 20 million? For some perspective, we might note that Barack Obama was elected the 44th president of the United States in 2009, 228 years after the first president was elected. That means the United States elects a new president on average every $(228/44) = 5.3$ years. Over 2000–2007, 4.1 million children were born in the United States per year. At that rate, $5.3 \times 4.1 \approx 22$ million Americans are born over 5.3 years, of whom one on average will be elected president. A randomly chosen American child thus has about a 1 in 22 million chance of being elected President

someday. One way of portraying aviation risk is to note that a child at a US airport has roughly the same chance of eventually becoming President as of perishing in an aviation accident on her next flight.¹

ARE SOME AIRLINES SAFER THAN OTHERS?

The tables might seem to suggest that, if flying between the First-World and the Developing-World, it is safer to travel on a First-World airline than a Developing-World one. But such reasoning could falter because of the statistical problem called the *ecological fallacy* [5]. To understand the fallacy, consider the three statements:

- John is better in mathematics than Bill.
- I have a problem in trigonometry.
- Therefore, I should contact John rather than Bill.

There is a logical problem in this sequence of statements. Perhaps, trigonometry is Bill's strong point, and John's weak point. In that case, I would do well to contact Bill. More generally, a statement that might be true in the aggregate does not have to apply in each specific instance. In the context of aviation, it could be fallacious to suggest that, because First and Developing-World airlines show a large aggregate difference in safety, that difference must apply on every subset of their routes.

To determine whether First-World carriers are safer than Developing-World airlines on routes on which the two groups compete, namely, between First-World and Developing-World cities, one should bypass overall statistics and compare fatal accident records on these specific routes. When Barnett and Wang [4] did so, they found that the Q-statistic was *the same* for both groups of carriers over 1987–1996: approximately 1 in 600,000. When Barnett [6] investigated the issue some years later, the result was the same: the Q-statistic was approximately

¹The risk goes up, however, if we consider criminal/terrorist acts, as we will in Table 2.

1 in 1.5 million on both First-World and Developing-World airlines.

In the United States, there have been suggestions that regional jet flights are less safe than larger jets operated by “mainline” carriers. But the data do not bear those suspicions out: there was one fatal accident with no survivors over 2000–2008 on a US regional jet, and the Q-value for these flights as a group was 1 in 20 million. That statistic is almost identical to the figure for the larger US jets, which suffered two fatal accidents with no survivors on roughly twice as many flights as the regional carriers.

More generally, available data suggest that when two airlines fly nonstop on the same route, very rarely is there an empirical basis for believing that one carrier is safer than the other.

OR/MS AVIATION RISK ANALYSIS

OR/MS can do more than simply document progress in reducing passenger mortality risk. It can help in the decision making that is essential to such progress. OR/MS methods have underlay data analyses and simulations that allow quantification of the extent to which new technologies and policies reduce risk to air travelers. The methods have also allowed estimates of the costs of new measures, and have thus facilitated the cost/benefit analyses that distinguish worthwhile innovations from others.

Aircraft fire safety is one domain in which OR/MS has contributed to major progress. Assessing the effectiveness of a new strategy to prevent, suppress, or slow the spread of fires is a complex endeavor. It involves mathematical modeling, but it especially requires devising, performing, and analyzing appropriate experiments. Such activities have long taken place at the Federal Aviation Administration’s (FAA) Technical Center in Atlantic City, as have other activities that allowed estimation of the costs (as opposed to the benefits) of implementing new strategies [7,8]. One consequence of such efforts is the greater use of fire-retardant materials in aircraft cabins. When Delta Air Lines Flight 1141 crashed on takeoff in Dallas in 1988,

14 people lost their lives. But it has been estimated that, absent changes in cabin materials that slowed the spread of fire, the death toll might have been four times as high.

OR/MS ideas also contributed to an emotional safety debate, on whether small children in planes should be required to sit in child-restraint seats rather than travel in the laps of their parents. These seats would offer greater safety in some emergencies, and would presumably force parents to buy tickets for these children rather than carry them for free. Data analyses indicated that the safety benefit of child-restraint seats was surprisingly small: if mandated, the seats would save the lives of an expected two children every 5 years [9]. And that calculation does not even consider a key point: Raising the cost of air travel with small children would lead some parents to drive rather than fly. That substitution would not only reduce the “lives saved” estimate under the mandate, but would also induce additional child deaths in road travel. Calculations showed that, because travel by car is less safe than travel by air, the net effect of the diversion would be to *increase* child deaths, and thus yield less safety rather than more. In 2005, FAA declined to require child-restraint seats on airplanes on these grounds.

A continuing danger in aviation is the threat of collisions, both on the ground and in the air. OR/MS has long been involved in risk analysis in this area [10]. While hazards like fires on airplanes might largely be things of the past, increases in air traffic raise the fear that collision risk will worsen in the future.

The dangers of collisions start on the ground: the worst aviation accident in history was a 1977 runway crash that killed 583 people. Simple probability models suggest that runway collision risk should vary not with the level of traffic at an airport, but rather with the *square* of the level. Thus, a doubling of traffic would cause a quadrupling of risk. Nor are these models alarmist: analyses of historical data about runway collisions and harrowing near-misses have empirically validated the quadratic model. An OR/MS study using the quadratic model and other

factors yielded a grim mid-range forecast: absent changes in technology or procedures, US airports could be expected to suffer 15 fatal runway collisions over 2003–2022, with a death toll of 700–800 [11].

Midair collisions involving scheduled passenger flights have all but disappeared from First-World skies. The last such event occurred in 1988, more than 200 million flights ago.² But the control arrangements in place now are likely to be changed soon. In Western Europe, there is strong pressure to replace the various national air traffic control systems with a harmonized one (a “single European sky”). In the United States, current airline itineraries—under which planes are confined to a network of prescribed flight paths—are slated to give way gradually to a set of “direct routings” from origin to destination. Such routings would lead to shorter flight times and lesser fuel consumption.

Such changes present safety challenges. Harmonizing dozens of air traffic systems is unlikely to be a straightforward process. And direct routings would certainly complicate any visual display of US flight paths. The moving dots that represent planes on controllers’ screens—which line up today like points on a grid—could in the future resemble gas molecules in random scatter. Moreover, a fundamental notion of industrial sociology is the “learning curve,” under which new procedures beget errors and difficulties that had not been anticipated. Thus, apart from specifics, any major changes in air traffic control in Europe and the United States could pose risk.

However, OR/MS models can sometimes reduce future risk simply by demonstrating that the risk is substantial. Prompted in part by forecasts about runway collisions, the US Federal Aviation Administration has undertaken a major program of technological innovation at the nation’s larger airports, introducing new Airport Surface Detection Equipment-Model X (ASDE-X)

Figure 1. Under direct routings, planes traveling from A to B and from C to D should get nowhere close to each other.

radar systems and runway status lights. Had they been in place, these technologies would have prevented many past runway collisions. The forecast of 700–800 deaths over 2003–2022 might turn out to be a “self-destroying prophecy,” which stimulated an effective response by showing that the price of inaction was intolerable.

As for the hazards posed by direct routings, OR/MS models and data analysis help clarify the situation. The models highlight the important point that while direct routings can increase midair-collision risk, they can also do some things that should reduce risk. Such routings would change the geometry of flight paths in ways that, in themselves, could make collisions less likely. For example, consider Fig. 1, which concerns one plane traveling from A to B and another from C to D. Under the present prescribed routes, the first plane might follow path A-E-F-B and the second, path C-E-F-D. These planes could therefore come in close proximity along their common segment EF. If each could take a direct routing, they would get nowhere near one another.

Moreover, there are reasons to believe that direct routings would reduce the angles at which flight paths would cross at a given altitude [12]. Were such angles to drop, the characteristics of some collision warning systems would mean that pilots might get more time to react to alerts about an impending collision. This extra time should increase the likelihood of avoiding the midair crash.

To be sure, it is not clear that these advantages of direct routings are more consequential than the potential problems. But mathematical models allow more precise thinking about the benefits and drawbacks

²There was, however, a midair collision over Germany in 2002 involving a DHL cargo plane and a Russian charter flight.

of the policy transition, and increase the chance that it will be implemented in a way that minimizes risk.

AVIATION SECURITY

How Great a Threat?

No reader of this essay needs a reminder about 9/11, the worst day ever in the history of commercial aviation. On that day, four hijacked planes crashed, two of them destroying the World Trade Center in New York and a third causing grievous harm at the Pentagon in Washington. In the aftermath of that catastrophe, aviation security changed in ways that have made the entire experience of flying more burdensome. Not everyone is convinced that the added effort has been well spent.

There are those who believe that aviation is no longer at any special risk. Terrorists who wish to “top” the 9/11 achievements could turn to biological, chemical, or nuclear attacks, or to strategies that cause convulsions in cyberspace or the economy. Even if terrorists use conventional weapons, why should they not turn from airplanes to subways, shopping malls, or seaports, which are essentially unprotected? The government’s National Commission on Terrorist Attacks on the United States [[13], the 9/11 Commission, at p. 351] warned that a preoccupation with aviation security because of the 9/11 events could be “fighting the last war.”

Perhaps this viewpoint makes sense, but [14] estimated as follows:

- More US civilians were killed by terrorists during air journeys than during any other form of activity.
- On a per-hour basis, the terrorism death risk was 600 times higher during air journeys than at other times.

And these statistics were based on *the 35-year period prior to 9/11!* During that time, terrorists killed Americans traveling by air on two dozen separate occasions, which included numerous attacks by grenade or bomb (the most famous being the destruction

of Pan Am 103 as it traveled from London to New York).

Nor have attempts to harm air travelers been absent since 9/11. In late 2001, the Shoe Bomber tried to destroy a transatlantic jet. A 2002 shoot-out at Los Angeles International Airport left several dead and injured. A deliberate fire felled a Chinese jet in 2002, while suicide bombers simultaneously destroyed two Russian jets in 2004. In 2006, a plot was uncovered to destroy approximately 10 transatlantic jets with liquid explosives. The year 2007 saw a firebombing at Glasgow airport, while 2008 saw another attempt to crash a Chinese jet plane. President Bush stated in 2007 that a post-9/11 terrorist plot was foiled which would have crashed a passenger jet into the tallest building on the US West Coast.

In short, it seems more plausible to view 9/11 as part of a continuing fascination with aviation than as an isolated, aberrant act. However, recounting lists of terrible events offers less systematic risk analysis than did earlier calculations about passenger death risk tied to accidents. Table 2 strives for greater balance by presenting Q-statistics associated with criminal and terrorist acts against jet aircraft.

We see from the parenthetical percentages in Table 2 that, in all decades and for both groupings of jet flights, deliberate acts against aviation have contributed less to passenger mortality risk than have accidents. We also see in the table some tendency of the absolute passenger risks from terrorism to decrease over time, though less monotonically and dramatically than risks of accidental death.

Yet there is something colossally missing in Table 2: the recognition that the victims of aerial terrorism can go far beyond air travelers. On September 11 2001, there were nine times as many people killed on the ground as on the four planes that were hijacked. There were as many deaths on 9/11 as in all First-World jet accidents *combined* over 1985–2008. The last thing we should do is cite Table 2 as evidence that security is a secondary threat compared to accidents.

Indeed, the terrorist threat to aviation is very different in nature from that tied to

Table 2. Death Risk per Scheduled Jet Flight Caused by Criminal/Terrorist Acts, by Decade 1960–2008

Period	First-World Death Risk per Flight		Developing-World Death Risk per Flight	
1960–1969	1 in 15 million	(7%)	0	(0%)
1970–1979	1 in 25 million (8%)	1 in 1 million	(19%)	
1980–1989	1 in 25 million	(15%)	1 in 3 million	(12%)
1990–1999	1 in 10 billion	(0%)	1 in 4 million	(11%)
2000–2008	1 in 30 million	(70%)	1 in 12 million	(16%)

Notes: Numbers in parenthesis express the preceding Q-value as a *percentage* of the corresponding Q-value for accidents in Table 1. Death risk refers to air travelers only.

accidents. Once an aerial hazard like wind shear has been dealt with, it is essentially gone for good. Terrorists, by contrast, can forever change their methods of attack. The relationship between the historical record and future dangers is much less clear for deliberate attacks on aviation than for accidents. It is certainly conceivable that, in years to come, terrorism will pose a greater threat to aviation than all other dangers combined.

What Should We Do?

It is widely recognized that we cannot pay any price, however enormous, to achieve any increase in security, however minuscule. But this truism does not provide guidance about how finite resources to prevent aerial terrorism might best be allocated. Because OR/MS has a rich tradition in large-scale optimization, it might seem ideally suited for devising an overall antiterrorist strategy. But the great difficulties of specifying costs, constraints, and benefits make the analysis of an aviation security system an inherently speculative venture [see [15] for a discussion about airport security screening].

Instead of trying to develop a sound aviation security policy in one fell swoop, we might do best to develop a policy step-by-step, considering one measure at a time, and assessing whether it might pass a cost-benefit test. Such a sequential analysis is not guaranteed to yield an “optimal” policy in any rigorous sense, but it might represent the best we can reasonably do. In the next section, we apply this sequential approach in two specific situations, reaching conclusions about what measures should (or even could)

be part of effort to protect aviation from terrorists.

No Laptops?

On September 10, 2006, *The New York Times* published an editorial titled “A Ban on Carry-On Luggage.” It noted that “laptops, digital cameras, mobile phones and other electronic devices” could be used to trigger a bomb, and urged that they be prohibited from the passenger cabins of commercial aircrafts. *The Times* acknowledged that “separating people from their laptops during flights would be painful,” but added that “some people could surely use the time to go over reading material, or even revert to pen and paper.” While expressing hope that the ban would eventually give way to technological advances, *The Times* concluded that “for now, the surest way to keep dangerous materials out of the cabin is to keep virtually all materials out of the cabin.”

The Times cannot be faulted for lack of audacity, or for the relentlessness of its logic. The main purpose of air transportation, after all, is to get people to their destinations swiftly and safely; providing a congenial environment en route is a desirable but secondary goal. If carry-on objects that could destroy the plane cannot be reliably detected, then maybe the objects should simply not be carried on.

Obviously, however, a ban on laptops would be highly disruptive for some travelers. The time not spent working on the airplane might result in less time at home with the children, or in leisure or civic activities. And it might be facetious to suggest that modern business activity can be accomplished with “pen and paper.”

How might the discussion extend beyond a shouting match? We can make progress if we are willing to accept two statistics at the outset:

- The RAND Corporation has estimated that another successful terrorist attack against US aviation would cost about \$15 billion to the nation [16].
- The US Congress has estimated that the monetized cost of each minute of air travel delay is 63 cents per passenger [17].

We might note that a typical First-World jet flight is about 1.5 h long [1], during roughly 1.25 h of which the use of laptops is now permitted. It seems clear that the total inconvenience to passengers caused by a laptop ban would be greater than that caused by a 1-min arrival delay. It also seems clear that a 4-h arrival delay would upset passengers more than 1.25 h without laptops. But then there must be some intermediate delay-equivalent X such that an average passenger would be indifferent between a delay of X min and a ban on laptops. Given that the cost of an X -min delay is $\$0.63 X$, we can infer a similar dollar cost for a laptop ban.

Preliminary estimates are that $X \approx 15$ min for US travelers (That figure takes account of the fact that, for those who would not have brought laptops on board, the cost of banning them is zero). That works out to a cost of $15 \times 0.63 = \$9.30$ per traveler which, when multiplied by 650 million US travelers per year, implies an annual cost of banning laptops of about \$6 billion per year.

Comparing \$6 billion with \$15 billion (the cost of successful terrorism) implies that the ban would be “cost-effective” if it prevented one terrorist act *every 2.5 years* (15/6). To put it another way, the ban would be cost-effective if the probability is at least 40% per year that, absent that ban, terrorists would succeed in destroying an aircraft by means that the ban would have prevented. We cannot calculate the relevant probability precisely, but the analysis reduces to the question: is it 40% or greater?

Both historical data and most expert opinion would answer this last question firmly in

the negative. In consequence, a ban on laptops might be so costly that it could be better to bear the risks of not imposing it than to accept the widespread disenchantment it would cause.

Out of Time?

One of the hallmarks of modern terrorism is that an initial act of violence often is followed almost immediately by other acts. 9/11 clearly fits that pattern, as do more recent attacks on transportation systems in Spain, Britain, Russia, and India. Other multiple near-simultaneous attacks have occurred in recent years in Japan, Israel, Morocco, Indonesia, Kenya, Saudi Arabia, Iraq, the Philippines, Jordan, and Egypt. Generally, all the attacks within a given series were of the same form (e.g., time-actuated bombings).

Suppose, therefore, that an airplane is suddenly destroyed by a terrorist bomb. Then there is every reason to fear that other planes aloft are in imminent danger of exploding. But what if anything can be done to save these planes? The situation is desperate: Because time is short, we might assume that any further bombs are highly unlikely to be located, let alone defused.

The first question to consider is: how much time would elapse between the explosion and a warning to the pilots of other endangered planes? The fall to the earth after an explosion takes time: Korean #007 hit the sea 10 min after it was shot down, and Pan Am #103 crashed into Lockerbie 7 min after it exploded. Additional time would pass between the plane’s hitting the ground and the confirmation of a crash, and further time would be required to notify aviation authorities, who could then contact air traffic controllers who in turn would notify pilots. In short, *10 min* is an optimistic estimate of the time between the first airborne explosion and any warning to other aircraft.

But would the endangered planes actually have 10 min? The answer would depend on how simultaneous the bombings in the series would be. In this connection, it is useful to

consider the *major bombings on air/rail systems since 9/11*, all of which claimed many lives:

Year	Place	Number/Timing of Bombings
2003	Russia	1
2004	Madrid	10 in 3 min
2004	Moscow	1
2004	Russia	2 in 2 min
2005	London	3 in 1 min
2006	Mumbai	7 in 11 min

The chart shows that, in four of the six events, there was one or more follow-up bombings. The total number of such subsequent blasts was 18. With a 10-min time lag, only one subsequent bombing—the last one in Mumbai—would not yet have occurred. Moreover, any sudden measures to depressurize an aircraft—probably the only feasible way to reduce the danger posed by a bomb explosion—are highly dangerous in their own right (Loss of cabin pressure has caused nearly 200 deaths in two jet crashes since 2005). Many lives could be lost in the attempts to mitigate a potential explosion, a good fraction of which would probably occur in response to false alarms.

Under these circumstances, we reach an agonizing conclusion: after an initial on-board explosion, the least dangerous response might be to *do nothing*. Most other planes in immediate danger could be beyond help, and rescue efforts could well cost more lives than they save. As optimization researchers know, even the “optimal” strategy against a terrible set of constraints can yield an extremely bad result.

In both of these instances, approximate cost-benefit analysis argued against the security measure under discussion. That situation does not always prevail: this author has argued elsewhere that positive-passenger bag match—under which no luggage would travel on an aircraft baggage compartment if the passenger who checked it did not show up—would be cost effective if it prevented one luggage bombing every 150 years [18]. The broader point is that, when applied on a case-by-case basis,

even simple cost-benefit analysis offers some insight into whether a particular security measure should be adapted into the overall security strategy. If the analysis seems a bit crude, perhaps nothing more elaborate can be defended when the background data are limited and imprecise.

FINAL REMARKS

In terms of preventing accidents, the world’s airlines have made enormous progress throughout the jet age. Indeed, in First-World nations, fatal air accidents are at the brink of extinction, a remarkable circumstance when we consider that, in every jet flight, there are hundreds of things that can go wrong that would kill everyone on board. Such progress reflects well on the airlines, aircraft manufacturers, government regulators, press, and flying publics. OR/MS plays a helpful role both in documenting improvements in safety and in facilitating the many technical analyses that are fundamental to such improvements.

Security threats are inherently more elusive than natural hazards as a menace to air travelers, and OR/MS methods can only reduce the uncertainties to a limited extent. But OR/MS models, often very simple, make it easier to think logically about devising a security strategy, and to distinguish between absurd security measures and others that are highly reasonable. The models work sharply against the paralyzing notion that, unless we can figure out everything about security policy, we can figure out nothing. They better enable us to harness perhaps the strongest weapons that we have against terrorists: our brains.

INTRODUCTION

This article provides a review of measures of risk and risk-value models that have been developed over the past 10 years to provide a new class of decision making models based on the idea of risk-value trade-offs. The measurement of risk has been a critical issue in decision sciences, finance, and other fields for many years. We focus on a preference-dependent measure of risk that can be used to derive risk-value models within both an expected utility framework and a non-expected utility framework. Although this measure of risk has some descriptive power for risk judgments, it is more normative in nature. We treat the issue of measures of perceived risk in a separate article in this collection (see *Axiomatic Models of Perceived Risk*).

Intuitively, individuals may consider their choices over risky alternatives by trading off between risk and return, where return is typically measured as the mean (or expected return) and risk is measured by some indicator of dispersion or possible losses. Markowitz [1–3] proposed variance as a

measure of risk, and a mean–variance model for portfolio selection based on minimizing variance subject to a given level of mean return. But arguments have been made that mean–variance models are appropriate only if the investor’s utility function is quadratic or the joint distribution of returns is normal. However, these conditions are rarely satisfied in practice. Markowitz also suggested semivariance as an alternative measure of risk. Some other measures of risk, such as lower partial moment risk measures and absolute standard deviation, have also been proposed in the financial literature [4]. However, without a common framework for risk models it is difficult to justify and evaluate these different measures of risk as components of a decision making process.

Expected utility theory is generally regarded as the foundation of mean-risk models and risk-return models [5–9]. However, expected utility theory has been called into question by empirical studies of risky choice [10–14]. This suggests that an alternative approach regarding the paradigm of risk-return trade-offs would be useful for predicting and describing observed preferences.

In the main stream of decision research, the role of risk in determining preference is usually considered implicitly. For instance, in the expected utility model [15], an individual’s attitude toward the risk involved in choices among risky alternatives is defined by the shape of his or her utility function [16,17]; and in some non-expected utility models, risk (or “additional” risk) is also captured by some nonlinear function over probabilities [12,18–20]. Thus, these decision theories are not, at least explicitly, compatible with the choice behavior based on the intuitive idea of risk-return trade-offs as often observed in practice. Therefore, they offer little guidance for this type of decision making.

In this article, we review our risk-value studies and provide an axiomatic measure of risk that is compatible with choice behavior

based on risk-value trade-offs. In particular, this framework unifies two streams of research: one in modeling risk judgments and the other in developing preference models. This synthesis provides risk-value models that are more descriptively powerful than other preference models and risk models that have been developed separately.

The remainder of this article is organized as follows: the next section describes a preference-dependent measure of risk with several useful examples. The section titled “Frameworks for Risk-Value Trade-Off” reviews the basic framework of our risk-value studies and related preference conditions. The section titled “Generalized Risk-Value Models” presents three specific forms of risk-value models. The concluding section summarizes the applicability of risk-value studies and discusses topics for future research.

STANDARD MEASURE OF RISK

As a first step in developing risk-value models, Jia and Dyer [21] propose a preference-dependent measure of risk, called a *standard measure of risk*. This general measure of risk is based on the converse expected utility of normalized lotteries with zero-expected values, so it is compatible with the measure of expected utility and provides the basis for linking risk with preference.

For lotteries with zero-expected values, we assume that the only choice attribute of relevance is risk. A riskier lottery would be less preferable and vice versa, for any risk-averse decision maker. Therefore, the riskiness ordering of these lotteries should simply be the reverse of the preference ordering. However, if a lottery has a nonzero mean, then we assume that the risk of that lottery should be evaluated relative to a “target” or reference level. The expected value of the lottery is a natural reference point for measuring the risk of a lottery.

Therefore, we consider decomposing a lottery X (i.e., a random variable) into its mean $\bar{X}$ and its standard risk, $X' = X - \bar{X}$, and the standard measure of risk is defined as

follows:

$$R(X') = -E[u(X')] = -E[u(X - \bar{X})], \quad (1)$$

where $u(\cdot)$ is a utility function [15] and E represents expectation over the probability distribution of a lottery.

One of the characteristics of this standard measure of risk is that it depends on an individual’s utility function. Once the form of the utility function is determined, we can derive the associated standard measure of risk over lotteries with zero means. More importantly, this standard measure of risk can offer a preference justification for some commonly used measures of risk so that the suitability of those risk measures can be evaluated.

If a utility function is quadratic, $u(x) = ax - bx^2$, where $a, b > 0$, then the standard measure of risk is characterized by the variance, $R(X') = bE[(X - \bar{X})^2]$. However, the quadratic utility function has a disturbing property; that is, it will be decreasing in x after a certain point and it exhibits increasing risk aversion. Since the quadratic utility function may not be an appropriate description of preference, it follows that variance may not be a good measure of risk (unless the distribution of a lottery is normal).

To obtain a related, but increasing utility function, consider a third-order polynomial (or cubic) utility model, $u(x) = ax - bx^2 + c'x^3$, where $a, b, c' > 0$. When $b^2 < 3ac'$, the cubic utility model is increasing. This utility function is concave, and hence risk averse for low outcome levels (i.e., $x < b/(3c')$), and convex, and thus risk seeking for high outcome values (i.e., $x > b/(3c')$). Such a utility function may be used to model a preference structure consistent with the observation that a large number of individuals purchase both insurance (a moderate outcome—small probability event) and lottery tickets (a small chance of a large outcome) in the traditional expected utility framework [22]. The associated standard measure of risk for this utility function can be obtained as follows:

$$R(X') = E[(X - \bar{X})^2] - cE[(X - \bar{X})^3], \quad (2)$$

where $c = c'/b > 0$. Model 2 provides a simple way to combine skewness with variance into a measure of risk. This measure of risk should be superior to variance alone since the utility function implied by Equation (2) has a more intuitive appeal than the quadratic one implied by variance. Further, since Equation 2 is not consistent with increasing risk aversion, it is more appropriate for prescriptive purposes than variance.

Markowitz [23] noted that an individual with the utility function that is concave for low outcome levels and convex for high outcome values will tend to prefer positively skewed distributions (with large right tails) over negatively skewed ones (with large left tails). The standard measure of risk (Eq. 2) clearly reflects this observation; that is, a positive skewness will reduce risk and a negative skewness will increase risk.

If an individual's preference can be modeled by an exponential or a linear plus exponential utility function, $u(x) = ax - be^{-cx}$, where $a \geq 0$, and $b, c > 0$, then its corresponding standard measure of risk (with the normalization condition $R(0) = 1$) is

$$R(X')E[e^{-c(X-\bar{X})} - 1]. \quad (3)$$

Bell [7] identified $E[e^{-c(X-\bar{X})}]$ as a measure of risk from the linear plus exponential utility model by arguing that the riskiness of a lottery should be independent of its expected value. Weber [24] also modified Sarin's [25] expected exponential risk model by requiring that the risk measure be location free.

If an individual is risk averse for gains but risk seeking for losses as suggested by Prospect Theory [12,26], then we can consider a piece-wise power utility model as follows:

$$u(x) = \begin{cases} ex^{\theta_1}, & \text{when } x \geq 0, \\ -d|x|^{\theta_2}, & \text{when } x < 0, \end{cases} \quad (4)$$

where e, d, θ_1 , and θ_2 are nonnegative constants. Applying Equation (1), the corresponding standard measure of risk is

$$R(X') = dE^{-}[|X - \bar{X}|^{\theta_2}] - eE^{+}[|X - \bar{X}|^{\theta_1}], \quad (5)$$

where $E^{-}[|X - \bar{X}|^{\theta_2}] = \int_{-\infty}^{\bar{X}} |x - \bar{X}|^{\theta_2} f(x) dx$, $E^{+}[|X - \bar{X}|^{\theta_1}] = \int_{\bar{X}}^{\infty} (x - \bar{X})^{\theta_1} f(x) dx$, and $f(x)$ is the probability density of a lottery.

The standard measure of risk (Eq. 5) includes several commonly used measures of risk in the financial literature as special cases. When $d > e > 0, \theta_1 = \theta_2 = \theta > 0$, and the distribution of a lottery is symmetric, then we can have $R(X') = (d - e)E[|X - \bar{X}|^{\theta}]$, which is associated with variance and absolute standard deviation if $\theta = 2$ and $\theta = 1$, respectively. This standard measure of risk is also related to the difference between the parameters d and e , which reflects the relative effect of loss and gain on risk. In general, if the distribution of a lottery is not symmetric, this standard measure of risk will not be consistent with the variance of the lottery even if $\theta_1 = \theta_2 = 2$, but it is still related to the absolute standard deviation if $\theta_1 = \theta_2 = 1$ [27].

Konno and Yamazaki [28] have argued that the absolute standard deviation is more appropriate for use in portfolio decision making than the variance, primarily due to its computational advantages. Dennenberg [29] argues that the average absolute deviation is a better statistic for determining the safety loading (premium minus the expected value) for insurance premiums rather than the standard deviation. These arguments suggest that the absolute standard deviation may be a more suitable measure of risk than variance in some applied contexts.

Another extreme case of Equation (5) arises when $e = 0$ (i.e., the utility function is nonincreasing for gains); then the standard measure of risk is a lower partial moment risk model $R(X') = dE^{-}[|X - \bar{X}|^{\theta_2}]$. When $\theta_2 = 2$, it becomes a semivariance measure of risk [1]; and when $\theta_2 = 0$, it reduces to the probability of loss.

In summary, some other proposed measures of risk are special cases of this standard measure of risk. The standard measure of risk is more normative in nature, as it is independent of the expected value of a lottery. To obtain more descriptive power and to capture perceptions of risk, we have also established measures of perceived risk that are based on a two-attribute structure: the mean of a lottery and its standard risk [30] as described

in a separate article in this encyclopedia (see *Axiomatic Models of Perceived Risk*).

FRAMEWORKS FOR RISK-VALUE TRADE-OFF

When we decompose a lottery into its mean and standard risk, then the evaluation of the lottery can be based on the trade-off between mean and risk. We assume a risk-value preference function $f(\bar{X}, R(X'))$, where f is increasing in $\bar{X}$ and decreasing in $R(X')$ if one is risk averse.

Consider an investor who wants to maximize his or her preference function f for an investment and also requires a certain level μ of expected return. Since f is decreasing in $R(X')$ and $\bar{X} = \mu$ is a constant, then maximizing $f(\bar{X}, R(X'))$ is equivalent to minimizing $R(X')$; that is, $\max \{f(\bar{X}, R(X')) | \bar{X} = \mu\} \Rightarrow \min \{R(X') | \bar{X} = \mu\}$. This conditional optimization model includes many financial optimization models as special cases by choosing different standard measures of risk; that is, Markowitz's mean-variance model, the mean-absolute standard deviation model, and the mean-semivariance model. Some new optimization models can also be formulated based on our standard measures of risk (Eqs 2 and 5).

In the conditional optimization problem, we do not need to assume an explicit form for the preference function f . The problem only depends on the standard measure of risk. However, we may argue that an investor should maximize his or her preference functions unconditionally in order to obtain the overall optimal portfolio. For an unconditional optimization decision, the investor's preference function must be specified. Here, we consider two cases for the preference function f : (i) when it is consistent with the expected utility theory and (ii) when it is based on a two-attribute expected utility foundation.

Let $\mathbf{P}$ be a convex set of all simple probability or lotteries $\{X, Y, \dots\}$ on a nonempty set $\mathbf{X}$ of outcomes, and Re be the set of real numbers (assuming $\mathbf{X} \in \text{Re}$ is finite). We define $\succ$ as a binary preference relation on $\mathbf{P}$.

Definition 1. For two lotteries $X, Y \in \mathbf{P}$ with $E(X) = E(Y)$, if $w_0 + X \succ w_0 + Y$ for some $w_0 \in \text{Re}$, then $w + X \succ w + Y$ for all $w \in \text{Re}$.

This is called the *risk-independence condition*. It means that for a pair of lotteries with a common mean, the preference order between the two lotteries will not change when the common mean changes; that is, preference between the pair of lotteries can be determined solely by the ranking of their standard risks.

Result 1. Assume that the risk-value preference function f is consistent with expected utility theory. Then f can be represented as the following standard risk-value form [21]:

$$f(\bar{X}, R(X')) = u(\bar{X}) - \varphi(\bar{X})[R(X') - R(0)] \quad (6)$$

if and only if the risk-independence condition holds, where $\varphi(\bar{X}) > 0$ and $u(\cdot)$ is a von Neumann and Morgenstern [15] utility function.

This model (Eq. 6) shows that an expected utility model could have an alternative representation if this risk-independence condition holds. If one is risk averse, then $u(\cdot)$ is a concave function and $R(X') - R(0)$ is always positive. $u(\bar{X})$ provides a measure of value for the mean. If we did not consider the riskiness of a lottery X , it would have the value $u(\bar{X})$. Since it is risky, $u(\bar{X})$ is reduced by an amount proportional to the normalized risk measure $R(X') - R(0) \cdot \varphi(\bar{X})$ is a trade-off factor that may depend on the mean. If we further require the utility model to be continuously differentiable, then it must be either a quadratic, exponential, or a linear plus exponential model [21].

There are also some other alternative forms of risk-value models within the expected utility framework under different preference conditions [8,9,31]. In addition, for nonnegative lotteries such as those associated with the price of a stock, Dyer and Jia [32] propose a relative risk-value framework in the form $X = \bar{X} \times (X/\bar{X})$ which decomposes the return into an average return $\bar{X}$ and a percentage-based risk factor $X/\bar{X}$. We find that this form of a risk-value

model is compatible with the logarithmic (or linear plus logarithmic) and the power (or linear plus power) utility functions [32]. Recent empirical studies by Weber *et al.* [33] indicate that this formulation may also be useful as the basis for a descriptive model of the sensitivity of humans and animals to risk.

However, the notion of risk-value trade-offs within the expected utility framework is very limited. Based on model 6, for example, consistency with expected utility imposes very restrictive conditions on the relationship between the risk measure $R(X') = -E[u(X - \bar{X})]$, the value measure $u(\bar{X})$, and the trade-off factor $\phi(\bar{X}) = u''(\bar{X})/u''(0)$ (for continuously differentiable utility models). In particular, the risk measure and the value measure must be based on the same utility function. However, a decision maker may deviate from this “consistency” and have different measures for risk and value if his choice is based on risk-value trade-offs.

In order to be more realistic and flexible in the framework of risk-value trade-offs, we consider a two-attribute structure $(\bar{X}, X')$ for the evaluation of a risky alternative X . In this way we can explicitly base the evaluation of lotteries on two attributes, mean and risk, so that the mean–risk (or risk-value) trade-offs are not necessarily consistent with the traditional expected utility framework.

We assume the existence of the von Neumann and Morgenstern expected utility axioms over the two-attribute structure $(\bar{X}, X')$ and require the risk-value model to be consistent with the two-attribute expected utility model, that is, $f(\bar{X}, R(X')) = E[U(\bar{X}, X')]$, where U is a two-attribute utility function. As a special case, when the relationship between $\bar{X}$ and X' is a simple addition, the risk-value model reduces to a traditional expected utility model, that is $f(\bar{X}, R(X')) = E[U(\bar{X}, X')] = E[U(\bar{X} + X')] = E[U(X)] = aE[u(X)] + b$, where $a > 0$ and b are constants.

To obtain some separable forms of the risk-value model, we need to have a risk-independence condition for the two-attribute structure. Let P^0 be the set of normalized lotteries with zero-expected values,

and $>$ a strict preference relation for the two-attribute structure.

Definition 2. For $X', Y' \in P^0$, if there exists a $w_0 \in \text{Re}$ for which $(w_0, X') > (w_0, Y')$, then $(w, X') > (w, Y')$ for all $w \in \text{Re}$.

This two-attribute risk-independence condition requires that if two lotteries have the same mean and one is preferred to the other, then transforming the lotteries by adding the same constant to all outcomes will not reverse the preference ordering. This condition is generally supported by our recent experimental studies [34].

Result 2. Assume that the risk-value preference function f is consistent with the two-attribute expected utility model. Then f can be represented as the following generalized risk-value form:

$$f(\bar{X}, R(X')) = V(\bar{X}) - \phi(\bar{X})[R(X') - R(0)] \quad (7)$$

if and only if the two-attribute risk-independence condition holds, where $\phi(\bar{X}) > 0$ and $R(X')$ is the standard measure of risk.

In contrast to the standard risk-value model (Eq. 6), the generalized risk-value model (Eq. 7) provides the flexibility of considering $V(\bar{X})$, $R(X')$, and $\phi(\bar{X})$ independently. Thus, we can choose different functions for the value measure $V(\bar{X})$ independent of the utility function. The expected utility measure is used only for the standard measure of risk. Even though expected utility theory has been challenged by some empirical studies for general lotteries, we believe that it should be appropriate for describing risky choice behavior within a special set of normalized probability distributions with the same expected values. For general lotteries with different means, however, our two-attribute risk-value model can deviate from the traditional expected utility preference. In fact, the generalized risk-value model can capture a number of decision paradoxes that violate the traditional expected utility theory [35].

If the utility function u is strictly concave, then $R(X') - R(0) > 0$ and Model 7 will reflect risk-averse behavior. In addition, if $V(\bar{X})$ is increasing and twice continuously differentiable, $\phi(\bar{X})$ is once continuously differentiable and $\phi'(\bar{X})/\phi(\bar{X})$ is nonincreasing; then the generalized risk-value model (Eq. 7) exhibits decreasing risk aversion if and only if $-V''(\bar{X})/V'(\bar{X}) > -\phi'(\bar{X})/\phi(\bar{X})$; and the generalized risk-value model (Eq. 7) exhibits constant risk aversion if and only if $-V''(\bar{X})/V'(\bar{X}) = -\phi'(\bar{X})/\phi(\bar{X})$ is a constant. Thus, if a decision maker is decreasingly risk averse and has a linear value function, then we must choose a decreasing function for the trade-off factor $\phi(\bar{X})$.

The basic form of the risk-value model may be further simplified if some stronger preference conditions are satisfied. When $\phi(\bar{X}) = k > 0$, Model 7 becomes the following additive form:

$$f(\bar{X}, R(X')) = V(\bar{X}) - k[R(X') - R(0)]. \quad (8)$$

When $\phi(\bar{X}) = -V(\bar{X}) > 0$, then Model 7 reduces to the following multiplicative form:

$$f(\bar{X}, R(X')) = V(\bar{X})R(X'), \quad (9)$$

where $R(0) = 1$ and $V(0) = 1$. In this multiplicative model, $R(X')$ serves as a value discount factor due to risk.

We describe measures of perceived risk based on the converse interpretation of the axioms of risk-value models in a companion article in this collection. These perceived risk models are simply a negative linear transformation of the risk-value model (Eq. 7) [30]. Our risk-value framework offers a unified approach to both, risk judgment and preference modeling.

GENERALIZED RISK-VALUE MODELS

According to the generalized risk-value model (Eq. 7), the standard measure of risk, value function, and trade-off factor can be considered independently. Some examples of the standard measure of risk $R(X')$ are provided in the section titled “Standard Measure of Risk.” The value measure $V(\bar{X})$ should be

chosen as an increasing function and may have the same functional form as a utility model. For appropriate risk-averse behavior, the trade-off factor $\phi(\bar{X})$ should be either a decreasing function or a positive constant; for example, $\phi(\bar{X}) = ke^{-b\bar{X}}$, where $k > 0$ and $b \geq 0$. We consider three types of risk-value models, namely, moments risk-value models, exponential risk-value models, and generalized disappointment models. For the corresponding perceived risk of each risk-value model, the reader is referred to the companion article in this collection (see **Axiomatic Models of Perceived Risk**).

Moments Risk-Value Models

People often use mean and variance to make trade-offs for financial decision making because they provide a reasonable approximation for modeling decision problems and are easy to implement [1–3, 36, 37]. In the past, expected utility theory has been used as a foundation for mean–variance models. Risk-value theory provides a better foundation for developing moments models that include the mean–variance model as a special case.

As an example, the mean–variance model, $\bar{X} - kE[(X - \bar{X})^2]$ where $k > 0$, is a simple risk-value model with variance as the standard measure of risk and a constant trade-off factor. Sharpe [36, 37] assumed this mean–variance model in his analysis for portfolio selection and the Capital Asset Pricing Model. However, under the expected utility framework, this mean–variance model is based on the assumptions that the investor has an exponential utility function and that returns are jointly normally distributed.

According to our risk-value theory, this mean–variance model is constantly risk averse. To obtain a decreasing risk-averse mean–variance model, we can simply use a decreasing function for the trade-off factor:

$$f(\bar{X}, R(X')) = \bar{X} - ke^{-b\bar{X}}E[(X - \bar{X})^2], \quad (10)$$

where $b, k > 0$.

For many decision problems, mean–variance models are an oversimplification.

Based on this risk-value framework, we can specify some richer moment models for risky decision making. First, let us consider the moment standard measure of risk (Eq. 2) for the additive risk-value model (Eq. 8):

$$f(\bar{X}, R(X')) = \bar{X} - k\{E[(X - \bar{X})^2] - cE[(X - \bar{X})^3]\}, \quad (11)$$

where $c, k > 0$. The three-moments model (Eq. 11) can be either risk averse or risk seeking, depending on the distribution of a lottery. For symmetric bets or lotteries not highly skewed (e.g., an insurance policy) such that $E[(X - \bar{X})^2] > cE[(X - \bar{X})^3]$, Model 11 will be risk averse. But for highly positive skewed lotteries (e.g., lottery tickets) such that the skewness overwhelms the variance, that is $E[(X - \bar{X})^2] < cE[(X - \bar{X})^3]$, then Model 11 will exhibit risk-seeking behavior. Therefore, an individual with preferences described by the moments model of Equation (11) would purchase both, insurance and lottery tickets simultaneously.

Markowitz [23] noticed that individuals have the same tendency to purchase insurance and lottery tickets whether they are poor or rich. This observed behavior contradicts a common assumption of expected utility theory that preference ranking is defined over ultimate levels of wealth. But whether our risk-value model is risk averse or risk seeking is determined only by the standard measure of risk, which is independent of an individual's wealth level (refer to the form of risk-value model in Eq. 4). In particular, for the three-moments model (Eq. 10), the change of wealth level only causes a parallel shift for $f(\bar{X}, R(X'))$; this will not affect the risk attitude and the choice behavior of this model. This is consistent with Markowitz's observation.

Exponential Risk-Value Models

If the standard measure of risk is based on exponential or linear plus exponential utility models, then the standard measure of risk is given by Equation (3). To be compatible with the form of the standard measure of risk, we can also use exponential functions, but with

different parameters, for the value measure $V(\bar{X})$ and the trade-off factor $\phi(\bar{X})$ for the generalized risk-value model (Eq. 7), which leads to the following model:

$$f(\bar{X}, R(X')) = -he^{-a\bar{X}} - ke^{-b\bar{X}}E[e^{-c(X-\bar{X})} - 1], \quad (10)$$

where a, b, c, h , and k are positive constants. When $a = b = c$ and $h = k$, this model reduces to an exponential utility model; otherwise, these two models are different. When $b > a$, Model 10 is decreasingly risk averse even though the traditional exponential utility model exhibits constant risk aversion.

As a special case, when $a = b$ and $h = k$, Model 10 reduces to the following simple multiplicative form:

$$f(\bar{X}, R(X')) = ke^{-a\bar{X}}E[e^{-c(X-\bar{X})}]. \quad (11)$$

This model is constantly risk averse, and therefore has the same risk attitude as an exponential utility model. It has more flexibility since there are two different parameters. This simple risk-value model can be used to explain some well-known decision paradoxes [35]

Choosing a linear function or a linear plus exponential function for $V(\bar{X})$ leads to the following models:

$$f(\bar{X}, R(X')) = \bar{X} - ke^{-b\bar{X}}E[e^{-c(X-\bar{X})} - 1] \quad (12)$$

and

$$f(\bar{X}, R(X')) = \bar{X} - he^{-a\bar{X}} - ke^{-b\bar{X}}E[e^{-c(X-\bar{X})} - 1]. \quad (13)$$

Model 12 is decreasingly risk averse. Model 13 includes a linear plus exponential utility model as a special case when $a = b = c$ and $h = k$. It is decreasingly risk averse if $b \geq a$.

Generalized Disappointment Models

Bell [38] proposed a disappointment model for decision making under uncertainty. According to Bell, disappointment is a psy-

chological reaction to an outcome that does not meet a decision maker's expectation. Bell used the mean of a lottery as a decision maker's psychological expectation. If an outcome smaller than the expected value occurs, the decision maker would be disappointed. Otherwise, the decision maker would be elated. Although Bell's development of the disappointment model has an intuitive appeal, his model is applicable only to lotteries with two outcomes.

Jia *et al.* [27] use the risk-value framework to develop a generalized version of Bell's disappointment model [38]. Consider the following piece-wise linear utility model:

$$u(x) = \begin{cases} ex & \text{when } x \geq 0, \\ dx & \text{when } x < 0, \end{cases} \quad (14)$$

where $d, e > 0$ are constant. Decision makers who are averse to downside risk or losses should have $d > e$, as illustrated in Fig. 1. The standard measure of risk for this utility model can be obtained as follows:

$$\begin{aligned} R(X') &= dE^-[|X - \bar{X}|] - eE^+[|X - \bar{X}|] \\ &= [(d - e)/2]E[|X - \bar{X}|], \end{aligned} \quad (15)$$

where $E^-[|X - \bar{X}|] = \sum_{x_i < \bar{X}} p_i |x_i - \bar{X}|$ and $E^+[|X - \bar{X}|] = \sum_{x_i > \bar{X}} p_i (x_i - \bar{X})$, and $E[|X - \bar{X}|]$

is the absolute standard deviation. Following Bell's basic idea [38], $dE^-[|X - \bar{X}|]$ represents a general measure of expected disappointment and $eE^+[|X - \bar{X}|]$ represents a general measure of expected elation. The overall psychological satisfaction is measured by $-R(X')$, which is the converse of the standard measure of risk (Eq. 15).

If we assume a linear value measure and a constant trade-off factor, then we can have the following risk-value model based on the measure of disappointment risk (Eq. 15):

$$\begin{aligned} f(\bar{X}, R(X')) &= \bar{X} - \{dE^-[|X - \bar{X}|] - eE^+[|X - \bar{X}|]\} \\ &= \bar{X} - [(d - e)/2]E[|X - \bar{X}|]. \end{aligned} \quad (16)$$

For a two-outcome lottery, Model 16 reduces to Bell's disappointment model. Thus, we call the risk-value model (Eq. 16)

Figure 1. A piece-wise linear utility function.

a “generalized disappointment model.” Note that the risk-value model [16] will be consistent with the piece-wise linear utility model (Eq. 14) when the lotteries considered have the same means. It is a risk-averse model when $d > e$.

Using his two-outcome disappointment model, Bell gave an explanation for the common ratio effect [38]. Our generalized disappointment model (Eq. 16) can explain the Allais Paradox [10,11], which involves an alternative with three outcomes [27]. Bell's model and Equation (16) both imply constant risk aversion and are not appropriate for decreasingly risk-averse behavior. To obtain a disappointment model with decreasing risk aversion, we can use a decreasing function for the trade-off factor:

$$f(\bar{X}, R(X')) = \bar{X} - ke^{-b\bar{X}}E[|X - \bar{X}|]. \quad (17)$$

Bell's disappointment model (Eq. 16) implies that disappointment and elation are proportional to the difference between the expected value and an outcome. We can use risk model (Eq. 5) to incorporate nonlinear functions for disappointment and elation in a more general form of the disappointment

model:

$$f(\bar{X}, R(X')) = \bar{X} - dE^-[|X - \bar{X}|^{\theta_2}] - eE^+[|X - \bar{X}|^{\theta_1}]. \quad (18)$$

When $\theta_1 = \theta_2 = 1$, this model reduces to Model 16. When $e = 0$ and $\theta_2 = 2$, Model 18 becomes a mean-semivariance model.

Finally, our generalized disappointment models are different from Loomes and Sugden's development [39]. In their basic model, disappointment (or elation) is measured by some function of the difference between the utility of outcomes and the expected utility of a lottery. They also assume a linear "utility" measure of wealth and the same sensation intensity for both disappointment and elation, so that their model has the form, $\bar{X} + E[D(X - \bar{X})]$, where $D(x - \bar{X}) = -D(\bar{X} - x)$, and D is continuously differentiable and convex for $x > \bar{X}$ (thus concave for $x < \bar{X}$). Even though this model is different from our generalized disappointment models (Eq. 18), it is a special case of our risk-value model with a linear measure of value, a constant trade-off factor, and a specific form of the standard measure of risk (i.e., $R(X') = -E[D(X - \bar{X})]$, where $D(x - \bar{X}) = -D(\bar{X} - x)$). Loomes and Sugden used this model to provide an explanation for the choice behavior that violates Savage's Sure-Thing Principle [40].

CONCLUSION

We have summarized our efforts to incorporate the intuitively appealing idea of risk-value trade-offs into decision making under risk. The risk-value framework ties together two streams of research: one in modeling risk judgments and the other in developing preference models, and unifies a wide range of decision phenomena including both, normative and descriptive aspects.

This development also refines and generalizes a substantial number of previously proposed decision theories and models, ranging from the mean-variance model in finance to the disappointment models in decision sciences. It is also possible to create many new risk-value models. Specifically, we

have discussed three classes of decision models based on this risk-value theory: moments risk-value models, exponential risk-value models, and generalized disappointment risk-value models. These models are very flexible in modeling preferences. They also provide new resolutions for observed risky choice behavior and the decision paradoxes that violate the independence axiom of the expected utility theory.

The most important assumption in this study is the two-attribute risk-independence condition, which leads to a separable form of risk-value models. Although some other weaker condition could be used to derive a risk-value model that has more descriptive power, this reduces the elegance of the basic risk-value form, and increases operational difficulty. Butler *et al.* [34] conducted an empirical study of this key assumption, and found some support for it. This study also highlighted some additional patterns of choices indicating that the translation of lottery pairs from the positive domain to the negative domain often results in the reversal of preference and risk judgments. To capture this phenomenon, we have extended risk-independence conditions to allow the trade-off factor in the risk-value models to change sign, and therefore to infer risk aversion in the positive domain and risk seeking in the negative domain. These generalized risk-value models provide additional insights into the reflection effects [12] and related empirical results [26,41,42].

Even though some other non-expected utility theories that have been proposed (e.g., Prospect Theory and other weighted utility theories) may produce the same predictions for the decision paradoxes as risk-value theory, it offers a new justification for them based on the appealing and realistic notion of risk-value trade-offs. In particular, since the role of risk is considered *implicitly* in these decision theories and models, they are not compatible with choice behavior that is based on the risk and mean return trade-offs often encountered in financial management, psychology, and other applied fields. Therefore, these theories and models offer little guidance in practice for this type of decision making. We believe that the potential for

contributions of these risk-value models in finance is very exciting. Applications of our risk-value models in other fields such as economics, marketing, insurance, and risk management are also promising.

Acknowledgments

INTRODUCTION

In a separate article in this collection (see *Axiomatic Measures of Risk and Risk-Value Models*), we discussed a standard measure of risk based on the converse of the expected utility of lotteries with zero-expected values, and showed how it could be used to derive risk-value models for risky choices within both an expected utility framework and a nonexpected utility framework [refer also [1–3]]. Though this standard measure of risk has some descriptive power for risk judgments, it is more normative in nature. In particular, since the standard measure of risk eliminates the effect of the mean of a lottery, it only measures the “pure” risk of the lottery, and may not be appropriate for modeling perceptions of risk. The purpose of this article is to review previously proposed models of perceived risk, with an emphasis on those perceived risk models that can be related to preference in a natural way. We then describe a two-attribute structure of perceived risk that allows the mean to impact judgments of risk perception and that can also be related to risk-value models for risky choice.

Over the last 30 years, researchers have expended much effort toward developing and testing models of the perceived riskiness of lotteries. Pollatsek and Tversky [4] provide an early summary of risk research that is still meaningful today:

The various approaches to study of risk share three basic assumptions. 1. Risk is regarded as a property of options (e.g., gambles, courses of action) that affects choices among them. 2. Options can be meaningfully ordered with respect to their riskiness. 3. The risk of an option is related in some way to the dispersion, or the variance, of its outcomes.

As stated in the first assumption, risk is a characteristic of a lottery that affects decisions. This is the primary motivation for studying the nature of perceived risk. A measure of perceived risk may be used as a variable in preference models, such as Coombs’ Portfolio theory [5–8] in which a choice among lotteries is a compromise between maximizing expected value and optimizing the level of perceived risk. However, the “risk” measure in Coombs’ Portfolio theory is left essentially undefined, and is considered to be an independent theory. This has stimulated a long stream of research on the measure of perceived risk.

Empirical studies have demonstrated that people are consistently able to order lotteries with respect to their riskiness, and that risk judgments satisfy some basic axioms [9,10]. Thus, as stated in the second assumption, the term “riskiness” should be both a meaningful and measurable characteristic of lotteries.

There have been many refinements to the third assumption as experimental results have exposed how perceived risk judgments change as a function of the characteristics of the lotteries considered. Some stylized facts regarding risk judgments include the following:

- Perceived risk increases when there is an increase in range, variance, or expected loss, for example [11].

- Perceived risk decreases if a constant positive amount is added to all outcomes of a lottery [9,12].
- Perceived risk increases if all outcomes of a lottery with zero-mean are multiplied by a positive constant greater than one [6].
- Perceived risk increases if a lottery with zero-mean is repeated many times [6].

These empirically verified properties provide basic guidelines for developing and evaluating measures of perceived risk.

In the following section, we give a review of previously proposed models of perceived risk and discuss their performance in empirical studies. In the section titled “Two-Attribute Models for Perceived Risk,” we present our measures of perceived risk based on a two-dimensional structure of the standard risk of a lottery and its mean show that it includes many of these previously proposed models as special cases. Finally, in the section titled “Conclusions,” we provide a summary and discuss the implications of the two-attribute perceived risk structure in decision making under risk.

REVIEW OF PERCEIVED RISK MODELS

The literature contains various attempts to define risk based on different assumptions about how perceived risk is formulated and how it evolves as the risky prospects under consideration are manipulated. In this section, we review some previously proposed models for perceived risk and their key assumptions. We focus on those that are closely related to a preference-dependent measure of risk that is compatible with traditional expected utility theory.

A more detailed review of perceived risk studies, including some measures of risk that are not closely related to preference, is provided by Brachinger and Weber [13]. We also exclude from our discussion the “coherent measures of risk” developed in the financial mathematics literature by Arztnar *et al.* [14,15], which produce results in monetary units (e.g., in dollars) that estimate the “expected shortfall” associated

with a portfolio. A recent review of the latter is given by Acerbi [16].

Studies by Coombs and his Associates

In early studies, risk judgments were represented by using the moments of a distribution and their transformations, that is, distributive models. Expected value, variance, skewness, range, and the number of repeated plays have been investigated as possible determinants of risk judgments [6,11,17]. Coombs and Huang [7] considered several composition functions of three indices corresponding to transformations on two-outcome lotteries, and their paper supported a distributive model that is based on a particular structure of the joint effect of these transformations on perceived risk. However, evidence to the contrary of such a distributive model was also found by Barron [18].

Coombs and Lehner [12] used distribution parameters as variables in the distributive model to test if moments of distributions are useful in assessing risk. For a lottery $(b + 2(1 - p)a, p; b - 2pa)$ (this means that the lottery has an outcome $(b + 2(1 - p)a)$ with probability p and an outcome $(b - 2pa)$ otherwise), which has a mean equal to b and range $2a$, the distributive model is represented by

$$R(a, b, p) = [\phi_1(a) + \phi_2(b)] \phi_3(p), \quad (1)$$

where R is a riskiness function and ϕ_1, ϕ_2 and ϕ_3 are real-valued monotonic functions defined on a, b and p , respectively. Coombs and Lehner [12] showed that the distributive model (Eq. 1) is not acceptable as a descriptive model of risk judgment. They concluded that complex interactions between the properties of risky propositions prevent a simple polynomial expression of the variables a, b and p from capturing perceived riskiness.

Coombs and Lehner [19] further considered perceived risk as a direct function of outcomes and probabilities, with no intervening distribution parameters. They assumed a bilinear model. In the case of just three outcomes (positive, negative, and zero), perceived risk is represented by the following

model:

$$R(X) = \phi_1(p)\phi_2(w) + \phi_3(q)\phi_4(l), \quad (2)$$

where w and l represent the positive and negative outcomes, with probabilities p and q ($p + q = 1$), respectively; R and ϕ_i ($i = 1, 2, 3$, and 4) are real-valued functions and X represents the lottery. The model assumes that a zero outcome and its associated probability have no direct effect on perceived risk. The form of model (2) is similar to Prospect theory [20]. Coombs and Lehner's [19] experiment supported the notion that perceived risk can be decomposed into contributions from good and bad components, and the bad components play a larger role than the good ones.

Pollatsek and Tversky's Risk Theory

An important milestone in the study of perceived risk is the axiomatization of risk theory developed by Pollatsek and Tversky [4]. They assumed four axioms for a risk system: (i) weak ordering; (ii) cancellation (or additive independence); (iii) solvability; and (iv) an Archimedean property. Let P denote a set of simple probability distributions or lotteries $\{X, Y, Z, \dots\}$ and $\geq_R$ be a binary risk relation (meaning at least as risky as). For convenience, we will use X, Y , and Z to refer to random variables, probability distributions or lotteries interchangeably. Pollatsek and Tversky showed that the four axioms imply that there exists a real-valued function R on P such that for lotteries X and Y : (i) $X \geq_R Y$ if and only if $R(X) \geq R(Y)$; (ii) $R(X \circ Y) = R(X) + R(Y)$, where " $\circ$ " denotes the binary operation of adding independent random variables; that is, the convolution of their density functions.

Pollatsek and Tversky considered three additional axioms: (v) positivity; (vi) scalar monotonicity; and (vii) continuity. These three additional axioms imply that R is a linear combination of mean and variance:

$$R(X) = -\theta \bar{X} + (1 - \theta)E[(X - \bar{X})^2], \quad (3)$$

where $0 < \theta = 1$.

However, the empirical validity of Equation (3) was criticized by Coombs and

Bowen [21], who showed that factors other than mean and variance, such as skewness, affect perceived risk. In Pollatsek and Tversky's system of axioms, the continuity condition based on the central limit theorem is directly responsible for the form of the mean-variance model (Eq. 3). Coombs and Bowen [21] showed that skewness impacts perceived risk even under multiple plays of a lottery when the effect of the central limit theorem modifies the effect of skewness.

Another empirically questionable axiom is the additive independence condition, which says that, for X, Y and Z in P , $X \geq_R Y$, if and only if $X \circ Z \geq_R Y \circ Z$. Fishburn [22] provides the following example of a setting where additive independence is unlikely to hold. Many people feel that a lottery $X = (\$1000, 0.01; -\$10,000)$ (i.e., X has probability 0.01 of a \$1000 gain, and a \$10,000 loss otherwise) is riskier than $Y = (\$2000, 0.5; -\$12,000)$. Consider another degenerate lottery Z that has a sure \$11,000 gain. Since $X \circ Z$ yields at least a \$1000 gain, whereas $Y \circ Z$ results in a loss of \$1000 with probability 1/2, it seems likely that most people would consider $Y \circ Z$ to be riskier than $X \circ Z$. This risk judgment pattern is inconsistent with additive independence. Empirical studies have also failed to support the independence condition [23,24].

Nevertheless, some of Pollatsek and Tversky's axioms are very appealing, such as positivity and scalar monotonicity. Because they are important to the present article, we briefly introduce them here. According to the positivity axiom, if K is a degenerate lottery with an outcome $k > 0$, then $X \geq_R X \circ K$ for all X in P . In other words, the addition of a positive sure-amount to a lottery would decrease its perceived risk. This quality is considered an essential property of perceived risk and has been confirmed by several empirical studies (e.g., [9,12]).

Another appealing axiom in Pollatsek and Tversky's theory is scalar monotonicity, which says, for all X, Y in P with $E(X) = E(Y) = 0$, (i) $\beta X \geq_R X$ for $\beta > 1$; (ii) $X \geq_R Y$ if and only if $\beta X \geq_R \beta Y$ for $\beta > 0$. This axiom asserts that, for lotteries with

zero expectation, risk increases when the lottery is multiplied by a real number $\beta > 1$ [also refer to [6]], and that the risk ordering is preserved upon a scale change of the lotteries (e.g., dollars to pennies). Pollatsek and Tversky regarded the positivity axiom and part (i) of the monotonicity axiom as necessary assumptions for any theory of risk.

In a more recent study, Rotar and Sholomitsky [25] weakened part (ii) of the scalar monotonicity axiom (coupled with some other additional conditions) to arrive at a more flexible risk model that is a finite linear combination of cumulants of higher orders. This generalized risk model can take into account additional characteristics of distributions such as skewness and other higher order moments. However, because Rotar and Sholomitsky's risk model still retains the additive independence condition as a basic assumption, their model would be subject to the same criticisms regarding the additivity of risk.

Luce's Risk Models and Others

Subsequent to the criticisms of Pollatsek and Tversky's risk measure, Luce [26] approached the problem of risk measurement in a different way. He began with a multiplicative structure of risk. First, Luce considered the effect of a change of scale on risk; multiplying all outcomes of a lottery by a positive constant. He assumed two simple possibilities, an additive effect and a multiplicative effect, presented as follows:

$$R(\alpha * X) = R(X) + S(\alpha) \quad (4)$$

or

$$R(\alpha * X) = S(\alpha)R(X), \quad (5)$$

where α is a positive constant and S is a strictly increasing function with $S(1) = 0$ for Equation (4) and $S(1) = 1$ for Equation (5). Luce's assumptions, Equations (4) and (5), are related to Pollatsek and Tversky's [4] scalar monotonicity axiom. But an important difference is that Pollatsek and Tversky only applied this assumption to the lotteries with zero expected values. As we will see later,

this may explain why Luce's models have not been supported by experiments.

Then, Luce considered two ways in which the outcomes and probabilities of a lottery could be aggregated into a single number. The first aggregation rule is analogous to the expected utility form and leads to an expected risk function:

$$R(X) = \int_{-\infty}^{\infty} T(x)f(x) dx = E[T(X)], \quad (6)$$

where T is some transformation function of the random variable X and $f(x)$ is the density of lottery X . In the second aggregation rule, the density goes through a transformation before it is integrated,

$$R(X) = \int_{-\infty}^{\infty} T^+[f(x)] dx, \quad (7)$$

where T^+ is some nonnegative transformation function. The combinations of the two decomposition rules, Equations (4) and (5), and the two aggregation rules, Equations (6) and (7), yield four possible measures of risk as follows:

1. By Equations (4) and (6),

$$\begin{aligned} R(X) = & a \int_{x \neq 0} \log|x| dx \\ & + b_1 \int_{-\infty}^0 f(x) dx \\ & + b_2 \int_0^{\infty} f(x) dx, \quad a > 0. \end{aligned} \quad (8)$$

2. By Equations (5) and (6),

$$\begin{aligned} R(X) = & a_1 \int_{-\infty}^0 |x|^\theta dx \\ & + a_2 \int_0^{\infty} x^\theta dx, \quad \theta > 0. \end{aligned} \quad (9)$$

3. By Equations (4) and (7),

$$\begin{aligned} R(X) = & -a \int_{-\infty}^{\infty} f(x) \log f(x) dx \\ & + b, \quad a > 0, b = 0. \end{aligned} \quad (10)$$

4. By Equations (5) and (7),

$$R(X) = a \int_{-\infty}^{\infty} f(x)^{1-\theta} dx, \quad a, \theta > 0. \quad (11)$$

Luce's risk models did not receive positive support from an experimental test by Keller, Sarin and Weber [9]. As Luce himself noted, an obvious drawback of the models (Eq. 10 and 11) is that both measures require that risk should not change if we add or subtract a constant amount to all outcomes of a lottery. This is counter to intuition and to empirical evidence [9,12]. Luce's absolute logarithmic measure (Eq. 8) is also neither empirically valid [9] nor prescriptively valid [27]. In Keller *et al.*'s experiment [9], only the absolute power model (Eq. 9) seems to have some promise as a measure of perceived risk.

Following Luce's work, Sarin [27] considered the observation that when a constant is added to all outcomes of a lottery, perceived risk should decrease. He assumed that there is a strictly monotonic function S such that for all lotteries and any real number β ,

$$R(\beta \circ X) = S(\beta)R(X). \quad (12)$$

Together with the expectation principle in Equation (6), this yields an exponential form of risk model,

$$R(X) = kE(e^{cX}), \quad (13)$$

where $kc < 0$.

Luce's and Sarin's models employ the expectation principle, which was first postulated for risk by Huang [28]. The expectation principle—an application of the independence axiom of expected utility theory—means that the risk measure R is linear under convex combinations:

$$R(\lambda X + (1 - \lambda)Y) = \lambda R(X) + (1 - \lambda)R(Y), \quad (14)$$

where $0 < \lambda < 1$. Empirical studies have suggested that this assumption may not be valid for risk judgments [9,19]. Weber and Bottom [10] showed, however, that the independence axiom is not violated for risk judgments,

but that the culprit is the so-called probability accounting principle [29]. These findings cast doubt on any perceived risk models based on the expectation principle, including Luce's logarithmic model (Eq. 8) and power model (Eq. 9) and Sarin's exponential model (Eq. 13).

Sarin also generalized the simple expectation principle using Machina's [30] non-expected utility theory and extended Luce's model (Eqs 8 and 9) into some more complicated risk models. However, since risk judgment is not identical to choice preference under risk, Sarin's proposal needs to be tested empirically.

Luce and Weber [29] proposed a revision of Luce's original power model (Eq. 8) based on empirical findings. This Conjoint Expected Risk (CER) model has the following form:

$$\begin{aligned} R(X) = & A_0 \Pr(X = 0) + A_+ \Pr(X > 0) \\ & + A_- \Pr(X < 0) \\ & + B_+ E[X^{K_+} | X > 0] \Pr(X > 0) \\ & + B_- E[|X|^{K_-} | X < 0] \Pr(X < 0), \end{aligned} \quad (15)$$

where A_0, A_+ , and A_- are probability weights, and B_+ and B_- are weights of the conditional expectations, raised to some positive powers, K_+ and K_- . The major advantage of the CER model is that it allows for asymmetric effects of transformations on positive and negative outcomes. Weber [31] showed that the CER model describes risk judgments reasonably well. One possible drawback of the CER model is that the lack of parsimony provides the degrees of freedom to fit any set of responses.

Weber and Bottom [10] tested the adequacy of the axioms underlying the CER model and found that the conjoint structure assumptions about the effect of change of scale transformations on risk hold for negative outcome lotteries, but not for positive outcome lotteries. This suggests that the multiplicative independence assumption [i.e., for positive (or negative) outcome-only lotteries X and Y , $X \geq_R Y$ if and only if $\beta X \geq_R \beta Y$ for $\beta > 0$] may not be valid. Note that Pollatsek and Tversky's [4] scalar monotonicity axiom is identical to multiplicative independence

but is only assumed to hold for lotteries with zero expected values.

Fishburn's Risk Systems

Fishburn [32,33] explored risk measurement from a rigorous axiomatic perspective. In his two-part study on axiomatizations of perceived risk, he considered lotteries separated into gains and losses relative to a target, say 0. Then the general set P of measures can be written as $P = \{(\alpha, p; \beta, q) : \alpha \geq 0, \beta \geq 0, \alpha + \beta \leq 1, p \in P^-, q \in P^+\}$, where α is the loss probability, p is the loss distribution given a loss, β is the gain probability, q is the gain distribution given a gain, $1 - p - q$ is the probability for the target outcome 0, and P^- and P^+ are the sets of probability measures defined on loss and gain, respectively. The risk measure in this general approach satisfies $(\alpha, p; \beta, q) \geq_R (\gamma, r; \delta, s)$, if and only if $R(\alpha, p; \beta, q) \geq R(\gamma, r; \delta, s)$.

Fishburn assumed that there is no risk if and only if there is no chance of getting a loss, which implies $R = 0$ if and only if $\alpha = 0$. This rules out additive forms of risk measures such as $R(\alpha, p; \beta, q) = R_1(\alpha, p) + R_2(\beta, q)$, but allows forms that are multiplicative in losses and gains; for example, $R(\alpha, p; \beta, q) = \rho(\alpha, p) * \tau(\beta, q)$. If ρ and τ are further decomposable, then the risk measure can be

$$R(\alpha, p; \beta, q) = \left[\rho_1(\alpha) \int_{x < 0} \rho_2(x) dp(x) \right] \times \left[1 - \tau_1(\beta) \int_{y > 0} \tau_2(y) dq(y) \right]. \quad (16)$$

According to Fishburn [33], the first part of this model measures the “pure” risk involving losses and the second measures the effect of gains on the risk. In the multiplicative model in Equation (16), gains proportionally reduce risk independent of the particular (α, p) involved (unless the probability of a loss, α , is zero, in which case there is no risk to be reduced). Fishburn did not suggest functional forms for the free functions

in his models, so it is difficult to test them empirically.

In summary, since the pioneering work of Coombs and his associates' on perceived risk, several formal theories and models have been proposed. But none of these risk models is fully satisfactory. As Pollatsek and Tversky [4] wrote, “. . . our intuitions concerning risk are not very clear and a satisfactory operational definition of the risk ordering is not easily obtainable.” Nevertheless, empirical studies have observed a remarkable consistency in risk judgments [9,10] suggesting the existence of robust measures of perceived risk.

TWO-ATTRIBUTE MODELS FOR PERCEIVED RISK

In this section, we propose two-attribute models for perceived risk based on the mean of a lottery and the standard measure of risk that is discussed in another article in this collection. In particular, our measures of perceived risk can be incorporated into preference models based on the notion of risk-value trade-offs. For the purpose of application, we suggest several explicit functional forms for the measures of perceived risk.

A Two-Attribute Structure for Perceived Risk

A common approach in previous studies of perceived risk is to look for different factors that are responsible for risk perceptions underlying a lottery, such as mean and variance or other risk dimensions, and then consider some separation or aggregation rules to obtain a new measurement model (see Payne [34] for a review). Jia and Dyer [2] decomposed a lottery X into its mean $\bar{X}$ and its standard risk, $X' = X - \bar{X}$, and proposed a standard measure of risk based on expected utility theory:

$$R(X') = -E[u(X')] = -E[u(X - \bar{X})] \quad (17)$$

where $u(\cdot)$ is a von Neumann and Morgenstern [35] utility function. The mean of a lottery serves as a status quo for measuring the standard risk. See the complementary article (see *Axiomatic Measures of Risk*

and Risk-Value Models) in this collection for a summary of this development.

The standard measure of risk has many desirable properties that characterize the “pure” risk of lotteries. It can provide a suitable measure of perceived risk for lotteries with zero expected values as well. However, the standard measure of risk would not be appropriate for modeling people’s perceived risk for general lotteries since the standard measure of risk is independent of expected value or any certain payoffs. That is, if $Y = X + k$, where k is a constant, then $Y' = Y - \bar{Y} = X - \bar{X} = X'$. As we discussed earlier, empirical studies have shown that people’s perceived risk decreases as a positive constant amount is added to all outcomes of a lottery.

To incorporate the effect of the mean of a lottery on perceived risk, we consider a two-attribute structure for evaluating perceived risk; that is, $(\bar{X}, X')$. In fact, a lottery X can be represented by its expected value $\bar{X}$ and the standard risk X' exclusively, for example, $X = \bar{X} + X'$. Thus, $(\bar{X}, X')$ is a natural extension of the representation of the lottery X . This two-attribute structure has an intuitive interpretation in risk judgment. When people make a risk judgment, they may first consider the variation or uncertainty of the lottery, measured by X' , and then take into account the effect of expected value on the uncertainty perceived initially, or vice versa.

To develop our measure of perceived risk formally, let $\mathbf{P}$ be the set of all simple probability distributions, including degenerate distributions, on a nonempty product set, $\mathbf{X}_1 \times \mathbf{X}_2$, of outcomes, where $\mathbf{X}_i \subseteq \text{Re}$, $i = 1, 2$, and Re is the set of real numbers. For our special case, the outcome of a lottery X on $\mathbf{X}_1$ is fixed at its mean $\bar{X}$; thus, the marginal distribution on $\mathbf{X}_1$ is degenerate with a singleton outcome $\bar{X}$. Because $\bar{X}$ is a constant, the two “marginal distributions” $(\bar{X}, X')$ are sufficient to determine a unique distribution in $\mathbf{P}$.

Let $>_{\bar{\mathbf{R}}}$ be a strict risk relation, $\sim_{\bar{\mathbf{R}}}$ an indifference risk relation, and $\geq_{\bar{\mathbf{R}}}$ a weak risk relation on $\mathbf{P}$. We assume a two-attribute case of the expectation principle and other necessary conditions analogous to those of multiattribute utility theory (e.g., Refs 36 and 37) for the risk ordering $>_{\bar{\mathbf{R}}}$ on $\mathbf{P}$ such

that for all $(\bar{X}, X'), (\bar{Y}, Y') \in \mathbf{P}$, $(\bar{X}, X') >_{\bar{\mathbf{R}}} (\bar{Y}, Y')$ if and only if $R_p(\bar{X}, X') > R_p(\bar{Y}, Y')$, where R_p is defined as follows:

$$R_p(\bar{X}, X') = E[U_R(\bar{X}, X')] \quad (18)$$

and U_R is a real-valued function unique up to a positive linear transformation. Note that because the marginal distribution for the first attribute is degenerate, the expectation, in fact, only needs to be taken over the marginal distribution for the second attribute, which in turn is the original distribution of a lottery X normalized to a mean of zero.

Basic Forms of Perceived Risk Models

Model (18) provides a general measure of perceived risk based on two attributes, the mean and standard risk of a lottery. In order to obtain separable forms of perceived risk models, we make the following assumptions about risk judgments:

Assumption 1. For $X', Y' \in \mathbf{P}^0$, if there exists a $w^0 \in \text{Re}$ for which $(w^0, X') >_{\bar{\mathbf{R}}} (w^0, Y')$, then $(w, X') >_{\bar{\mathbf{R}}} (w, Y')$ for all $w \in \text{Re}$.

Assumption 2. For $X', Y' \in \mathbf{P}^0$, $(0, X') >_{\bar{\mathbf{R}}} (0, Y')$, if and only if $X' >_{\mathbf{R}} Y'$.

Assumption 3. For $(\bar{X}, X') \in \mathbf{P}$, then $(\bar{X}, X') >_{\bar{\mathbf{R}}} (\bar{X} + \Delta, X')$ for any constant $\Delta > 0$.

Assumption 1 is an independence condition, which says that the risk ordering for two lotteries with the same mean will not switch when the common mean changes to any other value. Compared with Pollatsek and Tversky’s [4] additive independence condition, Assumption 1 is weaker since it features a pair of lotteries with the same mean and a common constant rather than a common lottery. Coombs [8] considered a similar assumption for a riskiness ordering; that is, $X \geq_{\mathbf{R}} Y$, if and only if $X + k \geq_{\mathbf{R}} Y + k$, where $E(X) = E(Y)$ and k is a constant. However, our formulation is based on a two-attribute structure, which leads to a separable risk function for $\bar{X}$ and X' , as we shall discuss.

Assumption 2 postulates a relationship between the two risky binary relations, $>_{\bar{\mathbf{R}}}$

and $>_R$ (where $>_R$ is a strict risk relation on P^0), so that for any zero expected lotteries, the risk judgments made by $R_p(0, X')$ and by the standard measure of risk $R(X')$ are consistent. The last assumption implies that if two lotteries have the same “pure” risk, X' , then the lottery with a larger mean will be perceived less risky than the one with a lower mean as suggested by previous studies (e.g., Refs 9 and 12).

Result 1. The two-attribute perceived risk model of Equation (18) can be decomposed into the following form [38]:

$$R_p(\bar{X}, X') = g(\bar{X}) + \psi(\bar{X})R(X'), \quad (19)$$

if and only if Assumptions 1–3 are satisfied, where $\psi(\bar{X}) > 0$, $g'(\bar{X}) < -\psi'(\bar{X})R(X')$, and $R(X')$ is the standard measure of risk.

According to this result, perceived risk can be constructed by a combination of the standard measure of risk and the effect of the mean. Result 1 postulates a constraint on the choice of functions $g(\bar{X})$ and $\psi(\bar{X})$ in Equation (19). If $\psi(\bar{X})$ is a constant, then the condition $g'(\bar{X}) < -\psi'(\bar{X})R(X')$ becomes $g'(\bar{X}) < 0$; that is, $g(\bar{X})$ is a decreasing function of $\bar{X}$. Otherwise, a nonincreasing function $g(\bar{X})$ and a decreasing function $\psi(\bar{X})$ should be sufficient to satisfy the condition $g'(\bar{X}) < -\psi'(\bar{X})R(X')$ when $R(X') > 0$.

For risk judgments, we may require that any degenerate lottery should have no risk (e.g., Refs 39–41). The concept of risk would not be evoked under conditions of certainty; no matter how bad a certain loss may be, it is a sure thing and, therefore, riskless. This point of view can be represented by the following assumption.

Assumption 4. For any $w \in \text{Re}$, $(w, 0) \sim_{\tilde{R}} (0, 0)$.

Result 2. The two-attribute perceived risk model of Equation (19) can be represented as follows [38]:

$$R_p(\bar{X}, X') = \psi(\bar{X})[R(X') - R(0)] \quad (20)$$

if and only if Assumptions 1–4 are satisfied, where $\psi(\bar{X}) > 0$ is a decreasing function of the mean $\bar{X}$, $R(X')$ is the standard measure of risk, and $R(0) = -u(0)$ is a constant.

When $g(\bar{X}) = -R(0)\psi(\bar{X})$ as required by Assumption 4, the general risk model of Equation (19) reduces to the multiplicative risk model of Equation (20). This multiplicative risk model captures the effect of the mean on perceived riskiness in an appealing way; increasing the mean reduces perceived riskiness in a proportional manner.

Finally, note that the two-attribute perceived risk models (Eqs 19 and 20) are not simple expected forms; we decompose a lottery into a two-attribute structure and only assume the expectation principle holds for normalized lotteries with zero expected values. For general lotteries with nonzero expected values, the underlying probabilities of lotteries can influence the standard measure of risk in a nonlinear fashion via $g(\bar{X})$, $\psi(\bar{X})$. Thus, models of Equations (19) and (20) avoid the drawbacks of expected risk models because the two-attribute expected utility axioms will not generally result in linearity in probability in the perceived risk models.

Relationship between Perceived Risk and Preference

An important feature of the two-attribute approach to modeling risk is that the derived measures of perceived risk can be treated as a stand alone primitive concept *and* can also be incorporated into preference models in a clear fashion. As summarized in the complimentary article, we proposed a risk-value theory for preference modeling also by decomposing a lottery into a two-attribute structure, the mean of the lottery and its standard risk.

A general form of the risk-value model can be represented as follows:

$$f(\bar{X}, X') = V(\bar{X}) - \phi(\bar{X})[R(X') - R(0)] \quad (21)$$

where $f(\bar{X}, X')$ represents a preference function based on the mean of a lottery and its standard risk, $V(\bar{X})$ is a subjective value measure for the mean of a lottery, $\phi(\bar{X}) > 0$ is

a trade-off factor that may depend on the mean, and the other notations are the same as in Equation (20). In general, a decreasing trade-off factor $\phi(\bar{X})$ is required in risk-value theory, which implies that the intensity of the risk effect on preference decreases as a positive constant amount is added to all outcomes of a lottery. Since the risk-value model (Eq. 21) is based on the two attribute expected utility axioms and the perceived risk model (Eq. 19) is derived by using the reverse interpretation of the same axioms, the two types of models must be a negative linear transformation of each other, that is, $f(\bar{X}, X') = -a R_p(\bar{X}, X') + b$, where $a > 0$ and b are constants. Several previously proposed measures of perceived risk also have the implication that their converse forms may be used for preference modeling (e.g., [4, 27, 30]).

The relationships between the functions in the models (Eqs (19) and (21)) can be clarified by transforming the perceived risk model (Eq. 19) into another representation similar to the risk-value model (Eq. 21). When $X = \bar{X}$, Equation (19) becomes $R_p(\bar{X}, 0) = g(\bar{X}) + \psi(\bar{X})R(0)$. Let $h(\bar{X}) = R_p(\bar{X}, 0)$, then $g(\bar{X}) = h(\bar{X}) - \psi(\bar{X})R(0)$. Substituting this into Equation (19), we obtain an alternative representation of the perceived risk measure, $R_p(\bar{X}, X') = h(\bar{X}) + \psi(\bar{X})[R(X') - R(0)]$. Based on our risk-value theory (Result 1), we can have $h(\bar{X}) = -aV(\bar{X}) + b$, and $\psi(\bar{X}) = a\phi(\bar{X})$, where $a > 0$ and b are constants.

The measure of perceived risk (Eq. 20) has more intuitive appeal in constructing preference based on risk-value trade-offs. Substituting $\phi(\bar{X}) = (1/a)\psi(\bar{X})$ into Equation (21), we have $f(\bar{X}, X') = V(\bar{X}) - (1/a)\psi(\bar{X})[R(X') - R(0)] = V(\bar{X}) - (1/a)R_p(\bar{X}, X')$. This representation is consistent with an explicit trade off between perceived risk and value in risky decision making. This provides a clear link between a riskiness ordering and a preference ordering, and shows an explicit role of risk perceptions in decision making under risk.

Some Examples

When $g(\bar{X})$ is linear, $\psi(\bar{X})$ is constant and $R(X')$ is variance, the perceived risk model (Eq. 19) reduces to Pollatsek and Tversky's

[4] mean-variance model as a special case. But Pollatsek and Tversky's risk model may be considered oversimplified. To obtain Rotar and Sholomitsky's [25] generalized moments model, the standard measure of risk should be based on a polynomial utility model.

We can select some appropriate functional forms for $g(\bar{X})$, $\psi(\bar{X})$ and $R(X')$ to construct specific instances of Equation (19). In our complementary article, we have proposed some explicit models for the standard measure of risk $R(X')$. Those models can be used directly in constructing functional forms of perceived risk models (Eqs 19 and 20). An example for $\psi(\bar{X})$ is $\psi(\bar{X}) = ke^{-b\bar{X}}$, where $k > 0$ and $b \geq 0$ (when $b = 0$, $\psi(\bar{X})$ becomes a constant k), and a simple choice for $g(\bar{X})$ is $g(\bar{X}) = -a\bar{X}$, where $a > 0$ is a constant. Some functional forms of the perceived risk model (Eq. 19) based on these choices of $\psi(\bar{X})$ and $g(\bar{X})$ are the following:

$$R_p(\bar{X}, X') = -a\bar{X} + ke^{-b\bar{X}}E[e^{-c(X-\bar{X})}], \quad (22)$$

$$R_p(\bar{X}, X') = -a\bar{X} + ke^{-b\bar{X}}\{E[(X-\bar{X})^2] - cE[(X-\bar{X})^3]\}, \quad (23)$$

$$R_p(\bar{X}, X') = -a\bar{X} + e^{-b\bar{X}}\{dE^-[|X-\bar{X}|^{\theta_2}] - cE^+[|X-\bar{X}|^{\theta_1}]\}, \quad (24)$$

where $a, b, c, d, e, k, \theta_1$ and θ_2 are constants, $E^-[|X-\bar{X}|^{\theta_2}] = \sum_{x_i < \bar{X}} p_i |x_i - \bar{X}|^{\theta_2}$, $E^+[|X-\bar{X}|^{\theta_1}] = \sum_{x_i > \bar{X}} p_i |x_i - \bar{X}|^{\theta_1}$, and p_i is the probability associated with the outcome x_i . When $b = 0$, these perceived risk models become additive forms. For consistency with their corresponding risk-value models, we refer to Equation (22) as the exponential risk model, Equation (23) as the moments risk model, and Equation (24) as the disappointment risk model. The latter was introduced by Bell [42] and explored in more detail by Jia *et al.* [43].

Similarly, some examples of the multiplicative form of risk model (Eq. 20) are given as follows:

$$R_p(\bar{X}, X') = ke^{-b\bar{X}}E[e^{-c(X-\bar{X})} - 1], \quad (25)$$

$$R_p(\bar{X}, X') = ke^{-b\bar{X}}\{E[(X-\bar{X})^2] - cE[(X-\bar{X})^3]\}, \quad (26)$$

$$R_p(\bar{X}, X') = e^{-b\bar{X}} \{dE^- [|X - \bar{X}|^{\theta_2}] - eE^+ [|X - \bar{X}|^{\theta_1}]\}. \quad (27)$$

Research on financial risk and psychological risk (i.e., perceived risk) has been conducted separately in the past. The risk-value framework is able to provide a unified approach for dealing with the both types of risk. The standard measure of risk is more normative in nature and should be useful in financial modeling. For instance, the standard measure of risk in perceived risk models (Eqs 24 and 27) includes many financial risk measures as special cases [2]. Our perceived risk models show how financial measures of risk and psychological measures of risk can be related. In particular, for a given level of the mean value, minimizing the perceived risk will be equivalent to minimizing the standard risk since the expressions for $g(\bar{X})$ and $\psi(\bar{X})$ in Equation (19) become constants. Our measures of perceived risk provide a clear way to simplify the decision criterion of minimizing perceived risk as suggested, but never operationalized, in Coombs' Portfolio theory.

CONCLUSIONS

In this article, we have reviewed previous studies about perceived risk and focused on a two-attribute structure for perceived risk based on the mean of a lottery and its standard risk. Some of these risk measures also take into account the asymmetric effects of losses and gains on perceived risk. These measures of perceived risk can unify a large body of empirical evidence about risk judgments, and are consistent with the stylized facts regarding risk judgments listed in the introduction. For more details regarding the flexibility provided by the two-attribute structure for perceived risk see Jia *et al.* [38]; for details on the empirical validity of the assumptions behind the models, see Butler, Dyer and Jia [44].

In particular, these measures of perceived risk show a clear relationship between financial measures of risk and psychological measures of risk. They can also be incorporated into preference models in a natural way, based on a trade-off between perceived risk

and expected value. This shows an intuitively appealing connection between perceived risk and preference.

This development uses the expected value of a lottery as the reference point regarding the measures of perceived risk. The expected value is a convenient and probabilistically appealing reference point [2], which makes our risk models mathematically tractable and practically usable. There are other possible reference points that might be considered, such as an aspiration level, a reference lottery, or some other external reference point, such as zero. It would be interesting to consider these alternative reference points in our measures of perceived risk in future research.

BACKTRACK SEARCH TECHNIQUES AND HEURISTICS

CHRISTOPHE LECOUTRE
CRIL-CNRS Université
Lille-Nord de France,
Lens, France

Satisfying a set of constraints is known as an instance of the constraint satisfaction problem (CSP), which is the subject of intense research in both artificial intelligence and operations research. Practical solution of CSP instances usually involves *backtrack search*. This is a *complete* approach in which systematic exploration of the search space of an instance finds the full set of solutions or proves that no solution exists. By contrast, *incomplete* approaches, such as those based on local search, are not guaranteed to find a solution or to prove unsatisfiability. Unfortunately, backtrack search is not expected to terminate within polynomial time in the general case, unless $P = NP$. This is why there have been considerable efforts during the last three decades to maximize the practical efficiency of backtrack search. In particular, the development of adaptive heuristics has shown impressive progress in guiding search.

GENERAL DESCRIPTION

A (finite) constraint network (CN), P [1,2] is composed of a finite set of variables, denoted by $vars(P)$, and a finite set of constraints, denoted by $cons(P)$. Each variable x has an associated domain, denoted by $dom(x)$, that contains the finite set of (current) values that can be assigned to x . Each constraint c involves an ordered set of variables, called the *scope* of c . A constraint is defined by a relation, denoted by $rel(c)$, which contains the set of tuples allowed for the variables involved in c . A CN is said to be *satisfiable* iff it admits at least one solution, that is, there is an assignment of a value to every variable such that every constraint is satisfied.

An instance of the CSP, is defined by a CN, which is solved either by finding a solution or by proving unsatisfiability.

For example, the classical queens problem can be stated as follows: can we put n queens on a board of size $n \times n$ such that no two queens attack each other? Two queens attack each other iff they belong to the same row, the same column or the same diagonal. A natural CSP model of this problem involves the introduction of a variable per queen (attached to a column), whose domain contains row numbers. If the i th variable x_i is assigned the value j , it means that the i th queen is put in the square at the intersection of the i th column and the j th row. For the n -queens instance, we have a CN P such that $vars(P) = \{x_1, \dots, x_n\}$ with $dom(x_i) = \{1, \dots, n\}$, $\forall i \in 1 \dots n$, and $cons(P) = \{x_i \neq x_j \wedge |x_i - x_j| \neq |i - j| : i \in 1 \dots n, j \in 1 \dots n, i < j\}$ because we need a binary constraint per pair of variables (queens). Figure 1 shows the two solutions for the 4-queens instance. The first one is given by $\{x_a = 2, x_b = 4, x_c = 1, x_d = 3\}$ where here, variables are denoted by x_a, x_b, x_c , and x_d (instead of x_1, x_2, x_3 , and x_4), to clarify the correspondence with columns.

Within backtrack search [3–5], depth-first exploration instantiates variables and a backtracking mechanism deals with dead-ends. The depth-first search considers a different variable at each level and tries to extend (in turn) different complementary branching decisions concerning this variable. In its simplest form, each branching decision is an assignment of a value to a variable; this is followed by checking that every constraint covered by the current instantiation is satisfied individually. A more sophisticated strategy applies a filtering procedure after each assignment of a value to a variable; this procedure is intended to simplify the subsequent search or to show that a dead-end has been reached, which means that the current set of decisions cannot be extended to a solution. When a dead-end is encountered, one or more decisions must be retracted before continuing the quest for a solution. The process

Figure 1. Solutions of the 4-queens instance. (a) First solution. (b) Second solution.

of undoing decisions in order to escape from a dead-end is called *backtracking*.

Backtrack search systems have four main components: *branching* (how and which decisions to take to go forward to a solution?), *propagation* (how and which level of filtering to apply to reduce the search space at each step?), *backtracking* (how to go backward when a dead-end is encountered?) and *learning* (what information to collect during search so as to facilitate subsequent parts of the search?). Each of these components has many possible implementations; there has been much effort to identify the right combinations of implementations. In particular, the interplay between propagation and backtracking techniques has been debated for a long time.

SEARCH TREES AND BRANCHING DECISIONS

Backtrack search algorithms build *search trees*. A search tree is basically a rooted tree that allows us to visualize successive decisions performed by a backtrack search algorithm. Starting at the root node with the initial CN that must be solved, each step in the search derives a new CN. Each node in the search tree is associated with one such CN and each (directed) edge is associated with a search decision. The search tree grows during the search. More specifically, if the search has currently reached node v , then after taking a new (branching) decision δ , we insert into the search tree a new node v' , representing the new step of the search, and a new edge $\{v, v'\}$ labeled with δ . The

new edge $\{v, v'\}$ is directed from v to v' ; v is called the *parent* of v' and v' a *child* of v . $dn(v)$ is the set of decisions that label successive edges in the path from the root to node v . The CN associated with node v is $cn(v) = \phi(P^{\text{init}}|_{dn(v)})$, where P^{init} is the initial CN $P^{\text{init}}|_{dn(v)}$ is P^{init} modified after taking into account all decisions present in $dn(v)$, and ϕ corresponds to the filtering performed during search (i.e., after each taken decision). Typically, ϕ is a property called *local consistency* that allows us to remove some *inconsistent* values; an inconsistent value cannot lead to any solution. If $P' = \phi(P)$ then P' is said to be obtained after enforcing ϕ on P .

Figure 2 provides an example of a search tree. Every node in a search tree is either a *leaf* node or an *internal* node. A leaf node differs from an internal node in that a leaf node has no children. When an inconsistency is detected (typically because a domain becomes empty, which prevents us from reaching a solution) at node v during search, this is denoted by $cn(v) = \perp$ and v is a leaf node called a *dead-end*. The search backtracks when a dead-end is reached. Any node v in the search tree is the root of a subtree obtained by retaining only v and its descendants (with all related edges). A node v is fully explored when the search space of the CN $cn(v)$ has been fully explored. If v is a fully explored internal node such that $cn(v)$ is unsatisfiable, v is called an *internal dead-end*, and the subtree rooted at v is called a *refutation tree* of $cn(v)$. If v' is an internal dead-end, and is a child of node v such that $cn(v)$ is satisfiable, then v' is a *mistake node*. A (sub)tree containing no solution is said to be *fruitless*.

Branching decisions, also called *branching constraints*, split a CN $P = cn(v)$ associated with an internal node v of the search tree into two or more CNs, the union of which is equivalent to P in terms of solutions. Classical branching schemes impose decisions during search under a strategy of *enumeration* or *labeling* [6]. Enumeration and labeling, respectively, correspond to *binary branching* (or *two-way branching*) and *nonbinary branching* (or *d-way branching*). More specifically, with nonbinary branching, at each internal node v , an unfixed variable x (i.e., variable whose domain is not singleton) is

Figure 2. A search tree built by a backtrack search algorithm. Note that decisions are taken depth-first. P^{init} is the instance to be solved initially and ϕ corresponds to the filtering performed during search.

selected, and then for each value a in $\text{dom}(x)$, the assignment $x = a$ is considered, so there are altogether d branches leaving v , where d is the size of $\text{dom}(x)$ at node v . With binary branching, at each internal node v , a pair (x, a) is selected where x is an unfixed variable and a a value in $\text{dom}(x)$, and two cases are considered: the assignment $x = a$ and the refutation $x \neq a$, so there are exactly two branches leaving v . Both of these two schemes guarantee complete exploration of the search space.

When mentioning a backtrack search algorithm, it is important to indicate whether binary branching or nonbinary branching is employed. These two schemes are not equivalent; it has been shown that binary branching is more powerful (to refute unsatisfiable instances) than nonbinary branching [7]. Using the resolution proof system, Hwang and Mitchell show that there exist instances which require exponential search trees for backtracking with d -way branching, but have polynomial search trees for backtracking with two-way branching. Although various other kinds of decision (e.g., membership decisions when splitting domains or nonunary branching constraints) are possible, these are not commonly used in the solution of discrete CSP instances. Recent exceptions are effective use of *partitioning* [8] and *bundling* [9,10], where complementary decisions of the form $x \in D_x$ with $D_x \subset \text{dom}(x)$ are taken.

BACKTRACK SEARCH ALGORITHMS

A (backtrack) ϕ -search algorithm is a backtrack search algorithm that enforces a local consistency ϕ after each decision taken. Algorithm 1 is a general formulation of any backtrack ϕ -search algorithm that employs binary branching. This quite reasonably assumes that ϕ gives a level of consistency which (at least) allows detection of any unsatisfied constraint whose variables are all fixed. For example, if P contains the constraint $x = y$, then after decisions $x = a$ and $y = b$ are taken, ϕ enforced on $P|_{\{x=a, y=b\}}$ will detect an inconsistency (since $a \neq b$). This algorithm starts by enforcing ϕ on the given CN P (which is an input parameter), returning *false* if an inconsistency is detected. If all domains are single valued at line 4 then because of our assumption about ϕ , all constraints are necessarily satisfied, so a solution has been found, and *true* is returned. Each step of the binary branching algorithm selects a pair (x, a) and recursively calls the function *binary- ϕ -search* with decisions $x = a$ and $x \neq a$. Depending on the implementation of the logical operator $\vee$ at line 7, the algorithm finds a single solution (if $\vee$ is managed in short-circuit, that is to say, if $\vee$ does not evaluate the right operand when the left one evaluates to *true*) or finds all solutions (if any).

Algorithm 1. $\text{binary-}\phi\text{-search}(\text{in } P: \text{Constraint Network}): \text{Boolean}$

Output: *true* iff P is satisfiable

```

1  $P \leftarrow \phi(P)$ 
2 if  $P = \perp$  then
3   return false
4 if  $\forall x \in \text{vars}(P), |\text{dom}(x)| = 1$  then
5   // display the solution
6   return true
7 select a pair  $(x, a)$  from  $P$  such that  $|\text{dom}(x)| > 1$ 
8 return  $\text{binary-}\phi\text{-search}(P|_{[x=a]}) \vee \text{binary-}\phi\text{-search}(P|_{[x \neq a]})$ 

```

Figure 3. A binary search tree built by a backtracking algorithm. The i th value in the current domain of a variable x is denoted by $a_{x,i}$.

Figure 3 illustrates the binary branching process and shows the systematic exploration of two branches for each selected pair (x, a) . Classically, binary branching algorithms select left branches, which assign values, before right branches, which refute values. The main advantage of binary branching over nonbinary branching is the possibility of selecting, after each refutation, a variable different from the one involved in the last decision. For this reason, heuristics that control the search may be more reactive.

The example in Fig. 3 assumes that an unsatisfiable subtree is explored after assignments $x = a_{x,1}$, $y = a_{y,1}$, and $z = a_{z,1}$. After the refutation $z \neq a_{z,1}$, the next selected variable is again z , making this portion of the search

tree rather similar to one that could be built with nonbinary branching. However, along the path labeled with $x = a_{x,1}$ and $y \neq a_{y,1}$, the next branching decisions involve the variable z which is different from y . Here the search heuristic, perhaps learning from previous explorations of subtrees, has decided to branch on a different variable rather than insisting on y .

Finally, note that CNs are usually processed during a so-called *preprocessing* stage initiated before search. Preprocessing may be limited to enforcing a consistency ϕ , but it may also refer to more sophisticated methods such as those based on structural decomposition [11]. During the preprocessing stage, some data structures may also have to be initialized so as to be used later during search by some algorithms. Sometimes, preprocessing alone is sufficient to solve a CSP instance.

CONSTRAINT PROPAGATION

After each branching decision, a filtering process is run by enforcement of a local consistency that prunes some parts of the search space containing no solution. For example, ϕ as mentioned above, may correspond to (generalized) arc consistency (AC) [12]. This is the strongest form of local reasoning when constraints are considered independently. Intuitively, AC allows us to safely remove a value a for a variable x if there exists a constraint c involving x but accepting no tuple (built from the current domains) with value a for x ; we say that (x, a) has no support on c . For example, if x and y are two variables such that $\text{dom}(x) = \text{dom}(y) = \{1, 2\}$ and we have the constraint $x < y$, then the value 2

Figure 4. The six steps performed by MAC to solve the 4-queens instance.

for x as well as the value 1 for y can be both removed because they have no support on $x < y$. Interestingly, as soon as a local inference (corresponding to the removal of a value) is performed, the conditions to trigger new inferences may hold since variables are typically shared by several constraints. This mechanism of propagating the results of local inferences from constraints to constraints is called *constraint propagation* [13].

MAC [14–16] is the backtrack search algorithm that maintains (generalized) AC after each decision taken; when the domain of a variable becomes empty (so-called *domain wipe-out*) a dead-end has been reached. Figure 4 shows the search steps performed by MAC to solve the 4-queens instance. Queens (variables) are put (instantiated) in columns from left to right and values are assigned from 1 to 4. Hatched squares represent values removed from variable domains due to constraint propagation. For example, the square at column b and row 1 and the square at column b and row 2 are hatched in Fig. 4a because x_a has just been assigned the value 1 and there is a constraint between the variables x_a and x_b associated with the first two columns defined as: $x_a \neq x_b \wedge |x_a - x_b| \neq 1$. The reason the square at column b and row 3 is also hatched

is due to constraint propagation. Note that all branching decisions are shown. For example, after MAC puts the first queen onto the square of the chessboard at column a and row 1, Fig. 4a, a dead-end is reached and this square is then discarded as shown in Fig. 4b.

BACKTRACKING TECHNIQUES

When a dead-end is reached, conflicting decisions can be reviewed via *eliminating explanations* which are recorded during the search. Instead of backtracking to the most recent previous decision, so-called *chronological backtracking*, it may be helpful to jump back to the most recent decision among those that could possibly have caused the failure. This backward jump (or backjump) is a form of *intelligent backtracking*, also called *backjumping*, and can be managed so as to guarantee that no solution will be missed.

The relationship between *look-back* (efficient escape from dead-ends) and *look-ahead* (simplification of subsequent search), has been the subject of much investigation. MAC was used in the 1970s [14,17] with nonbinary branching, without backjumping and without dynamic variable ordering (presented in the section titled “Search Heuristics”). Nonchronological backtracking

was initiated with dependency-directed backtracking [18–20] and Prolog intelligent backtracking [21]. Early in the 1990s, the forward checking (FC) algorithm (introduced 10 years before [22,23]) associated with the variable ordering heuristic *dom* [23] and the conflict-directed backjumping (CBJ) technique [24] was considered to be the most efficient generic approach to solve CSP instances. In 1994, Sabin and Freuder [16] reintroduced MAC using binary branching and simple chronological backtracking. This algorithm was shown to be more efficient than FC and FC-CBJ; CBJ was considered to be useless to MAC, especially when MAC had a good variable ordering heuristic [25].

The situation subsequently became more confused. First, Bayardo and Shrag [26] showed that many large propositional satisfiability instances derived from real-world problems are easy when CSP look-back techniques are combined with the “Davis–Putnam” procedure [3]. Second, although theoretical results [27] showed that the backward phase is less useful when the forward phase is more advanced, some experiments on hard structured problems showed that combining CBJ with MAC can still produce significant improvements. Third, look-back techniques appeared to be improved by associating an eliminating explanation (or conflict set) with any value rather than with any variable. Indeed, refined eliminating explanations allows a stronger form of backjumping [28] and the possibility of saving much search effort with the principle of dynamic backtracking (DBT) [29]. Experimental results [28,30] showed that MAC can be outperformed by algorithms embedding such advanced look-back techniques. However, the next section will show that some form of learning, perhaps limited to a basic statistical form, is essential to the efficient guidance of search.

The use of eliminating explanations [29], as in CBJ, is now illustrated. An eliminating explanation for a pair (x, a) , denoted by $\text{expl}(x \neq a)$, is a subset of all decisions currently taken by the search algorithm, which explains why the value a has been removed from the domain of x . In Fig. 5, we suppose that we have an eliminating explanation

Figure 5. Eliminating explanations computed for values of y . As both branches $y = c$ and $y \neq c$ [c was the last value in $\text{dom}(y)$] have been explored, we have to backtrack.

for each value present in the initial domain of y , and have reached a dead-end. Taking the union of all eliminating explanations for values of y yields a set of decisions, called a *nogood*, that cannot be extended to a solution. Reasoning from this *nogood* allows us to safely backtrack up to $w = b$, the most recent decision in the *nogood*, and refute it globally; see Fig. 6. Further, we can compute an eliminating explanation $\text{expl}(w \neq b)$ from the *nogood*.

Figure 6. Backtrack guided by the *nogood* extracted from situation of Fig. 5.

SEARCH HEURISTICS

Two choices are made at each step within backtrack search. Before branching, the search algorithm selects first a variable x and then a value a in the current domain of x ; the global selection of a pair (x, a) is also possible but efficient implementations of this approach remains an open challenge. Thus, the search algorithm imposes an ordering on variables and on their values. However, finding an optimal ordering is at least as difficult as solving a CSP instance. This is why, in practice, ordering is determined by *heuristics*. A heuristic is a general guideline rule that is expected to lead to good results, but is not claimed to give optimal outcomes in every situation.

For backtrack search, a first general principle is that it is better to start by assigning variables that belong to the most difficult part(s) of the problem instance. This principle is derived from recognition that there is no point in traversing the easy part(s) of an instance and then backtracking repeatedly when it turns out that the first choices are incompatible with the remaining difficult part(s). Here the underlying *fail-first* principle, according to Haralick and Elliott [23], is: “To succeed, try first where you are most likely to fail.”

Value selection can be based on the *succeed-first* or *promise* principle, which comes from the simple observation that to find a solution quickly, it is better to move at each step to the most promising subtree, primarily by selecting a value that is most likely to participate in a solution. It is preferable to avoid branching on a value that is inconsistent, because this implies exploration of a fruitless subtree, which is clearly a waste of time if there is a solution elsewhere.

Although these two principles are somewhat contradictory (basically because all variables must be given a value whereas only a good value per variable has to be found), variable ordering can to some extent comply with both of them [31–33]. Various different measures of promise of variable ordering heuristics try to assess the ability of the heuristics to avoid making mistakes, that is,

to keep the search on the path to a solution regardless of the value ordering. There appears to be quite a complex relationship between promise and fail-firstness. For value ordering, the extent of adherence to both heuristics can also be assessed; first elements related to this can be found in Szymanek and O’Sullivan [34] and Lecoutre *et al.* [35].

When starting to build the search tree, the initial variable/value choices are particularly important. Bad choices near the root of the search tree may turn out to be disastrous because they lead to exploration of very large fruitless subtrees. To make good initial choices, one strategy is to select the first branching decisions with special care, perhaps calling sophisticated and expensive procedures for this purpose. Another strategy is to restart search several times [36], ideally learning some information each time in order to refine search guidance [37,38].

In what follows, we focus our attention to variable ordering because the order in which variables are assigned by a backtrack search algorithm has been recognized as a key issue for a long time. Using different variable ordering heuristics can drastically affect the efficiency of algorithms solving CSP instances. For example, introducing some form of randomization into a given variable ordering heuristic can cause great variability in performance. *Static* variable ordering heuristics keep the same ordering throughout the search, using only (structural) information about the initial state of search. *Dynamic* variable ordering heuristics take account of the current state of the instance being solved. These heuristics are dynamic because their ordering generally varies during the search. The well-known dynamic heuristic *dom* [5,23] orders variables in sequence of increasing size of domain, so a variable that has the smallest domain size is selected at each step. Variants of *dom* are the heuristics *dom + deg* [39] and *dom/deg* [25] that additionally take degrees of variables into account.

Static and (nonadaptive) dynamic variable ordering heuristics are relatively poor general-purpose heuristics. The remainder of

Figure 7. Two partial search trees built from the same instance P^{init} . We have v_1 and v_2 representing similar nodes, that is, nodes such that their associated constraint networks are identical. Unlike a static or dynamic variable ordering heuristic, an adaptive variable ordering heuristic can make a different selection at nodes v_1 and v_2 .

this section presents two adaptive heuristics that can reasonably be considered to be state of the art. A search-guiding heuristic is said to be *adaptive* when it makes choices that depend on the current state of the problem instance as well as previous states. Thus an adaptive heuristic learns, in the sense that it takes account of information concerning the subtree already been explored. Figure 7 illustrates the fact that an adaptive heuristic may behave differently when two similar nodes (i.e., two nodes such that their associated CNs are identical) are reached after exploring different subtrees.

A first family of adaptive heuristics is based on the concept of *impacts*. An impact is a measure of the effect of an assignment. More specifically, an impact is a measure of the relative amount of search space reduction that an assignment is expected to achieve. The impact of a variable is the “sum” of impacts of possible assignments to this variable. Impacts can be used in the heuristic selection of variables and values. The variable with highest impact is typically selected first. For this variable, the value with lowest impact is selected. It is important that impacts can be refined during search, allowing learning from experience. The use of impacts was studied initially by Geelen [40] and has been adaptively revisited by Refalo

[41] inspired by pseudo-costs that are widely used in integer programming.

Another family of adaptive heuristics is based on constraint weighting, which is an efficient mechanism for identifying hard parts of combinatorial problems. It was initially introduced to improve the performance of local search methods and/or Boolean satisfiability (SAT) solving [42–44]. Hybrid search techniques based on dynamic constraint weighting were also proposed in Mazure *et al.* [45] and Eidenberg and Faltings [46]. The principle of constraint weighting is quite simple:

1. associate a counter with each constraint c to denote the *weight* of c ,
2. increment the weight of a constraint c whenever a dead-end occurs due to propagation on c ,
3. at each branching point, select the variable with the highest weighted degree; the weighted degree of a variable x is the sum of the weights of the constraints involving x .

The practical effect of selecting first the variables with greatest weighted degrees is to examine first the locally inconsistent or hard parts of networks, in conformity with the fail-first principle. This variable ordering heuristic is denoted by *wdeg* [47], and a variant is *dom/wdeg*, which selects first the variable having the smallest ratio of current domain size to current weighted degree. These *conflict-directed* heuristics appear to outperform current intelligent backtracking methods [48]. But the robustness of heuristic *dom/wdeg* is best demonstrated by comparing it with classical heuristics on a wide range of problems. Figure 8 shows the results obtained on a large set of instances, including various series of random and structured instances, when using MAC with the adaptive heuristic *dom/wdeg* and with the representative classical heuristic *dom + deg*. In this scatter plot, each dot represents an instance and each axis represents the CPU time required to solve the instances with MAC using the heuristic labeling the axis. Many dots are located on the right side of the scatter plot, which means that *dom/wdeg*

Figure 8. Pairwise comparison (CPU time) of heuristics $dom/wdeg$ and $dom+deg$ when used by MAC to solve the instances chosen as benchmarks of the 2006 constraint solver competition (time out set to 1000 s per instance).

solves far more instances than $dom + deg$ within the allotted time.

BACKWARD AND FORWARD EQUATIONS FOR DIFFUSION PROCESSES

ARKA P. GHOSH

Department of Statistics, Iowa
State University, Ames, Iowa

In this article we discuss two partial differential equations (PDEs) that arise in the theory of continuous-time continuous-state Markov processes, which was introduced by Kolmogorov in 1931. Here, we focus only on Markov diffusion processes (see **Introduction to Diffusion Processes**) and describe the forward and backward equations for such processes. The forward equation is also known as *Fokker–Planck equation* (and was already known in the physics literature before Kolmogorov formulated these). We begin with a brief introduction to continuous-time continuous-state Markov processes, which are continuous analogs of discrete-time Markov chains (DTMCs) and continuous-time Markov chains (CTMCs), discussed earlier in the sections titled “Discrete-Time Markov Chains (DTMCs)” and “Continuous-Time Markov Chains (CTMCs)” in the encyclopedia, followed by some basic properties of Markov processes. Then we state the two equations and provide sketches of the proofs. Finally, we conclude the article with some specific examples and features of these equations.

PRELIMINARIES

Diffusion processes have been discussed in the article titled **Introduction to Diffusion Processes**. For simplicity of the exposition, we consider the following time-homogeneous version of the diffusion process for this section: A (time-homogeneous) Itô diffusion is a stochastic process $\{X(t)\}$ satisfying a stochastic differential equation of the form

$$\begin{aligned} dX(t) &= b(X(t))dt + \sigma(X(t))dW(t), \\ t > 0; X(0) &= x, \end{aligned} \quad (1)$$

where $\{W(t)\}$ is a (standard) Brownian motion and b, σ are functions that satisfy

$$|\sigma(x) - \sigma(y)| < D|x - y|; x, y \in \mathbf{R}.$$

It can be shown that for $\{\mathcal{F}_t^W\}, \{\mathcal{F}_t^X\}$, representing the filtrations generated by W and X ,

$$\mathcal{F}_t^X \subseteq \mathcal{F}_t^W. \quad (2)$$

Markov Property

The diffusion satisfies the *Markov property*: If f is a bounded measurable function, then $E^x[f(X(t+h))|\mathcal{F}_t^W] = E^{X(t)}[f(X(h))]$, where the superscript in the expectation represents that these are conditional expectations given $X(0) = x$. Thus, from Equation (2), we have that: $E^x[f(X(t+h))|\mathcal{F}_t^X] = E^{X(t)}[f(X(h))]$. This intuitively means that the (future) evolution of the diffusion process is completely specified by the current value of the process (and the knowledge of the history of the process is not necessary). Compare this property to the Markov property introduced in the context of Markov chains (discrete-time versions in the section titled “Discrete-Time Markov Chains (DTMCs)” and continuous-time versions in the section titled “Continuous-Time Markov Chains (CTMCs)” in the encyclopedia) above. In fact, the above property holds in a stronger sense, in which the time t can be replaced by a random (stopping) time τ (strong Markov property).

Infinitesimal Generator

For Markov processes, the infinitesimal generator is defined as

$$Af(x) = \lim_{t \downarrow 0} \frac{E^x(f(X(t))) - f(x)}{t}, \quad x \in \mathbf{R}. \quad (3)$$

The set of functions f for which the limit on the right side exists (for all x) is called the *domain of the operator*, and denoted by $\mathcal{D}_A$. For an Itô diffusion that we are concerned with, this operator is a second-order partial differential operator, and can be written

down explicitly as follows:

$$Af(x) = b(x)\frac{df}{dx} + \frac{1}{2}\sigma^2(x)\frac{d^2f}{dx^2}, \quad (4)$$

and $\mathcal{D}_A$ contains all twice-differentiable functions with compact support. This operator plays a fundamental role in the study of diffusion processes, and is relevant for understanding the forward and backward Kolmogorov equations for diffusions.

Examples

Here are generators of some basic examples of diffusion processes discussed in the article titled **Introduction to Diffusion Processes**. For a (general) Brownian motion (with drift b and diffusion coefficient $\sigma > 0$) the generator is

$$Af(x) = bf'(x) + \frac{1}{2}\sigma^2 f''(x). \quad (5)$$

For geometric Brownian motion process (with parameters b and σ), the generator is

$$Af(x) = bxf'(x) + \frac{1}{2}x^2\sigma^2 f''(x). \quad (6)$$

For Ornstein–Uhlenbeck process (with parameters b and σ), it is

$$Af(x) = -bxf'(x) + \frac{1}{2}\sigma^2 f''(x). \quad (7)$$

FORWARD AND BACKWARD EQUATIONS FOR DIFFUSION PROCESSES

These are two (partial) differential equations that characterize the dynamics of the distribution of the diffusion process. Kolmogorov's forward equation addresses the following: If at time t the state of the system is x , what can we say about the distribution of the state at a future time $s > t$ (hence the term *forward*). The backward equation, on the other hand, is useful when addressing the question that given that the system at a future time s has a particular behavior, what can we say about the distribution at time $t < s$. This imposes a terminal condition on the PDE, which is integrated backward in time, from s to t (hence the term

backward is associated with this). Historically, the forward equation was discovered (as the Fokker–Plank equation) before the backward equation. However, the backward equation is somewhat more general and we will describe that first.

The forward and backward equations are expressed in various equivalent forms. Here, we describe them in the following form, which illustrates the use of the terms forward and backward more clearly: Fix an interval $[0, T]$, and we will deal with $t \in [0, T]$.

Backward Equation

Let $g(x)$ be a bounded smooth (twice continuously differentiable having compact support) function, and let

$$u(t, x) = E^{x,t}(g(X(T))) \equiv E(g(X(T)) | X(t) = x). \quad (8)$$

Then u satisfies

$$\begin{aligned} \frac{\partial u}{\partial t} + Au &= 0, \text{ with the “terminal” condition} \\ u(T, x) &= g(x), \end{aligned} \quad (9)$$

where the right-hand side is to be interpreted as A (as in Equation (4)) applied to the $u(t, x)$ as a function of x .

Forward Equation

In addition, if $X(t)$ has a density $p(t, x)$, then for a probability density function $\mu(\cdot)$, the probability densities satisfy the following:

$$\begin{aligned} \frac{\partial}{\partial t} p(t, x) &= (A^* p)(t, x) \text{ with the initial} \\ \text{condition } p(0, x) &= \mu(x). \end{aligned} \quad (10)$$

Here A^* is the adjoint operator of A , defined as

$$\begin{aligned} A^* v(t, y) &= -\frac{\partial}{\partial y} (b(y)v(t, y)) \\ &\quad + \frac{1}{2} \frac{\partial^2}{\partial y^2} (\sigma^2(y)v(t, y)). \end{aligned} \quad (11)$$

Proof

We now provide a sketch of the proof of the backward equation (9). First, note that for the Markov (diffusion) process $\{X(t)\}$ with some transition probability function

$$P(t, x, A) = P(X(t) \in A | X(0) = x),$$

the following Chapman–Kolmogorov equation holds:

$$P(t + s, x, A) = \int P(t, x, du)P(s, u, A). \quad (12)$$

Recall the Chapman–Kolmogorov equation introduced earlier in the section titled “Discrete-Time Markov Chains (DTMCs)” in the encyclopedia in the context of Markov chains. Also note that for the diffusion in Equation (1), the following properties are satisfied for the transition probabilities

$$\begin{aligned} \lim_{t \rightarrow \infty} \frac{1}{t} \int_{\{|x-y| \geq \delta\}} P(t, x, dy) &= 0, \\ \lim_{t \rightarrow \infty} \frac{1}{t} \int_{\{|x-y| < \delta\}} (y-x)P(t, x, dy) &= b(x), \\ \lim_{t \rightarrow \infty} \frac{1}{t} \int_{\{|x-y| \geq \delta\}} (y-x)^2 P(t, x, dy) &= \sigma(x), \end{aligned} \quad (13)$$

for all $\delta > 0$. Informally, it means the following: in a small time interval, it has negligible probability of being away from x ; also, the mean and variance of the “displacements” of the diffusion process is approximately the drift and the diffusion coefficients, respectively. We will use these properties in the proofs of the forward and backward equations here. First, observe that from Equations (12) and (8) it follows that

$$u(t + h, x) = \int P(h, x, dy)u(t, y).$$

Hence,

$$\begin{aligned} \frac{u(t+h) - u(t)}{h} &= \frac{\int P(h, x, dy)[u(t, y) - u(t, x)]}{h} \\ &\approx \frac{1}{h} \int P(h, x, dy) \left[(y-x) \frac{\partial u(t, x)}{\partial x} \right. \\ &\quad \left. + \frac{1}{2} (y-x)^2 \frac{\partial^2 u(t, x)}{\partial x^2} \right], \end{aligned} \quad (14)$$

where the last expression follows from Taylor’s expansion, and the approximate equality is a consequence of Equation (13), for h small. Hence, by taking limit as $h \rightarrow 0$, using 13 and the form of the generator A in Equation (4), the backward equation follows.

Now we sketch the proof of the forward equation (10) using the backward equation as follows: Assume that the random variable $X(t)$ has a density $p(t, x)$ and hence, from Equation (8) and properties of conditional expectations, we have

$$\begin{aligned} E(g(X(T))) &= E(E^{x,t}(g(X(T)))) \\ &= \int u(t, x)p(t, x) dx. \end{aligned}$$

Since the left side is free of t , we get by taking derivatives with respect to t ,

$$0 = \int p(t, x) \frac{\partial u(t, x)}{\partial t} dx + \int \frac{\partial p(t, x)}{\partial t} u(t, x) dx. \quad (15)$$

Since u satisfies the backward equation (9), using the form of A in Equation (4), we get from Equation (15) that

$$\begin{aligned} 0 &= \int p(t, x) \left(-b(x) \frac{\partial u(t, x)}{\partial x} - \frac{1}{2} \sigma^2(x) \frac{\partial^2 u(t, x)}{\partial x^2} \right) dx \\ &\quad + \int \frac{\partial p(t, x)}{\partial t} u(t, x) dx. \end{aligned}$$

Finally, using integration by parts (which replaces x -derivatives of u by those of p), assuming that the integrals decay fast enough (as $|x| \rightarrow \infty$) and using the form of A^* in Equation (11), we get that

$$\int \left(-(A^*p)(x, t) + \frac{\partial p(t, x)}{\partial t} \right) u(t, x) dx = 0.$$

Since this equation should be true for all functions u , we get that $(A^*p)(x, t) = \frac{\partial p(t, x)}{\partial t}$, which proves the forward equation.

EXAMPLES

Here we discuss some special cases of the forward and backward diffusions.

Example 1 [Martingale Property].

When $b \equiv 0$, then the forward equation reduces to

$$\frac{1}{2} \frac{\partial^2}{\partial x^2} (\sigma^2(x)p(t, x)) = \frac{\partial}{\partial t} p(t, x). \quad (16)$$

Hence, using integration by parts, one gets

$$\begin{aligned} \frac{d}{dt} E[X(t)] &= \frac{d}{dt} \int_{-\infty}^{\infty} xp(x, t) dx \\ &= \int_{-\infty}^{\infty} x \frac{\partial}{\partial t} p(t, x) dx \\ &= \int_{-\infty}^{\infty} x \frac{1}{2} \frac{\partial^2}{\partial x^2} (\sigma^2(x, t)p(x, t)) dx \\ &= - \int_{-\infty}^{\infty} \frac{1}{2} \frac{\partial}{\partial x} (\sigma^2(x, t)p(x, t)) dx = 0. \end{aligned}$$

In other words, $E[X(t)]$ does not change with t . In fact, one can prove a stronger statement: the process $\{X(t)\}$ is a martingale, that is, $E[X(t) | \mathcal{F}_s^W] = X(s)$ for all $s < t$.

Example 2. Consider the Ornstein–Uhlenbeck process with parameters b and σ (see *Introduction to Diffusion Processes*), whose generator was discussed earlier (for simplicity, we assume $\sigma = 1$ here). The backward equation for this process follows from the general form of the Equation (9) and the generator in Equation (7)

$$\frac{\partial}{\partial t} u(t, x) = -bx \frac{\partial}{\partial x} u(t, x) + \frac{1}{2} \frac{\partial^2}{\partial x^2} u(t, x), \quad (17)$$

which can be solved explicitly. It turns out, with a change of variable, it reduces to the standard diffusion equation (16) (with $\sigma(x) \equiv 1$). From that, it can be deduced that the transition probability $P(t, x, \cdot)$ is the normal (Gaussian) probability with mean xe^{-bt} and variance parameter $\frac{(1-e^{-2bt})}{2b}$.

Example 3. Similarly, for the geometric Brownian motion process, one can get the forward equation by substituting $b(x) = bx, \sigma(x) = \sigma x$ in Equations (9) and (6). Solving these explicitly yields that the transition probability in this case is a log-normal

probability

$$P(t, x, A) = \int_A \frac{1}{\sigma y \sqrt{2\pi t}} \exp \left(-\frac{\log(y/x) - (b - \frac{1}{2}\sigma^2)t}{2\sigma^2 t} \right) dy.$$

Remark. The backward equation holds whenever b is continuous and $\sigma > 0$. But for the forward equation to hold, one clearly needs the derivatives of these two functions. In that sense, backward equation is more general than the forward equation. However, when such derivatives exist, one can show that there exists a “minimal” solution for the transition function $P(t, x, A)$ such that $u(\cdot, \cdot)$ in Equation (8) solves the backward equation. But this transition function in such cases need not be a “proper” probability. To guarantee that a proper transition probability can be obtained from these equation, one usually assumes additional boundary conditions. Different choices of such boundary conditions (e.g., absorbing boundary condition, reflecting boundary conditions etc.) uniquely characterize the associated process (see Chapter 10 of Ref. 1 for more discussion on this topic).

FURTHER READING

More details about these equations can be found in classical textbooks on probability, such as Ref. 1. Other references for these equations for diffusion processes are Refs 2–5, and so on. For students and researchers that are trying to study this material for the first time, more accessible references could be Refs 6 and 7. A reference for general Markov processes can be found in Ref. 8. For partial differential equations, in general, one is encouraged to consult Ref. 9.

As mentioned earlier, these equations are very important in physics and there is a vast literature [10–12] on this topic from the physics community as well. For applications to financial mathematics, see Refs 13 and 14. A general reference for students in operations research to learn stochastic

systems in general is Ref. 15. For more applications in queueing theory models involving diffusions processes, see Refs 16 and 17.

BASIC CP THEORY: CONSISTENCY AND PROPAGATION (ADVANCED)

CHRISTIAN BESSIERE
University of Montpellier,
Montpellier, France

Constraint reasoning involves various types of techniques to tackle the inherent intractability of the problem of satisfying a set of constraints. Constraint propagation is one of those types of techniques. Constraint propagation embeds any reasoning which consists in explicitly forbidding values or combinations of values for some variables of a problem because a given subset of the constraints cannot be satisfied otherwise. For instance, in a problem containing two variables x_1 and x_2 taking integer values in $1..10$, and a constraint specifying that $|x_1 - x_2| > 5$, by propagating this constraint we can forbid values 5 and 6 for both x_1 and x_2 . Removing these values is a way to reduce the space of combinations that will be explored by a search mechanism.

The concept of constraint propagation can be found in other fields under different kinds and names. (See, for instance, the propagation of clauses by “unit propagation” in propositional calculus [1].) Nevertheless, it is in constraint reasoning that this concept appears in such a variety of forms, and in which its characteristics have been so deeply analyzed.

Constraint propagation can be presented along two main lines: *local consistencies* and *rules iteration*. Local consistencies define properties that the constraint problem must satisfy *after* constraint propagation. This way, the operational behavior is left completely open, the only requirement being to achieve the given property on the output. The rules iteration approach, on the contrary, describes the process of propagation itself. Rules are conditions on the kind of operations of reduction that can be applied to the problem. In this article, I will present constraint propagation mainly through local

consistency. Rules iteration will be briefly discussed at the end of the article.

BACKGROUND

A *constraint satisfaction problem (CSP)* involves finding solutions to a constraint network, that is, assignments of values to its variables that satisfy all its constraints. Constraints specify combinations of values that given subsets of variables are allowed to take. In this article, we are only concerned with CSPs where variables take their value in a *finite* domain. Without loss of generality, I assume these domains are mapped on the set $\mathbb{Z}$ of integers, and so, I consider only *integer* variables, that is, variables with a domain being a finite subset of $\mathbb{Z}$.

Definition 1 [Constraint]. A *constraint* c is a relation defined on a sequence of variables $X(c) = (x_{i_1}, \dots, x_{i_{|X(c)|}})$, called the *scheme* of c . c is the subset of $\mathbb{Z}^{|X(c)|}$ that contains the combinations of values (or *tuples*) $\tau \in \mathbb{Z}^{|X(c)|}$ that *satisfy* c . $|X(c)|$ is called the *arity* of c . Testing whether a tuple τ satisfies a constraint c is called a *constraint check*.

A constraint can be specified extensionally by the list of its satisfying tuples (or the list of its forbidden tuples), or intensionally by a formula that is the characteristic function of the constraint. Definition 1 allows constraints with an *infinite* number of satisfying tuples. Constraints of arity 2 are called *binary* and constraints of arity greater than 2 are called *nonbinary*.

Example 1. The constraint *alldifferent* $(x_1, x_2, x_3) \equiv (x_1 \neq x_2 \wedge x_1 \neq x_3 \wedge x_2 \neq x_3)$ allows the infinite set of 3-tuples in $\mathbb{Z}^3$ such that all values are different. The constraint $c(x_1, x_2, x_3) = \{(2, 2, 3), (2, 3, 2), (2, 3, 3), (3, 2, 2), (3, 2, 3), (3, 3, 2)\}$ allows the finite set of 3-tuples containing both values 2 and 3 and only them.

Definition 2 [Constraint network]. A *constraint network* (or *network*) is composed of:

- a finite sequence of integer variables $X = (x_1, \dots, x_n)$,
- a domain for X , that is, a set $D = D(x_1) \times \dots \times D(x_n)$, where $D(x_i) \subset Z$ is the finite set of values, given in extension, that variable x_i can take, and
- a set of constraints $C = \{c_1, \dots, c_e\}$, where variables in $X(c_j)$ are in X .

Given a constraint network N , I sometimes use X_N , D_N , and C_N to denote its sequence of variables, its domain, and its set of constraints. Given a set of variables $Y = \{x_{i_1}, \dots, x_{i_q}\} \subseteq X$, D^Y denotes the Cartesian product $D(x_{i_1}) \times \dots \times D(x_{i_q})$. According to Definitions 1 and 2, the variables X_N of a network N and the scheme $X(c)$ of a constraint $c \in C_N$ are sequences of variables, not sets. This is required because the order of the values matters for tuples in c . Nevertheless, it simplifies a lot the notations to consider sequences as sets when no confusion is possible. For instance, given two sequences W and Y , $W \subseteq Y$ means that the sequence W involves only variables that are in the sequence Y , whatever their ordering in the sequence. Given a tuple τ on a sequence Y of variables, and given a sequence $W \subseteq Y$, $\tau[W]$ denotes the restriction of τ to the variables in W , ordered according to W . Given $x_i \in Y$, $\tau[x_i]$ denotes the value of x_i in τ .

Backtracking algorithms are based on the principle of assigning values to variables until all variables are *instantiated*.

Definition 3 [Instantiation]. Given a network $N = (X, D, C)$,

- An *instantiation* I on $Y = (x_1, \dots, x_k) \subseteq X$ is an assignment of values $v_1, \dots, v_k$ to the variables $x_1, \dots, x_k$, that is, I is a tuple on Y . I can be denoted by $((x_1, v_1), \dots, (x_k, v_k))$ where (x_i, v_i) denotes the value v_i for x_i .

- An instantiation I on Y is *valid* if for all $x_i \in Y$, $I[x_i] \in D(x_i)$.
- An instantiation I on Y is *locally consistent* iff it is valid and for all $c \in C$ with $X(c) \subseteq Y$, $I[X(c)]$ satisfies c . If I is not locally consistent, it is *locally inconsistent*.
- A *solution* to a network N is an instantiation I on X which is locally consistent. The set of solutions of N is denoted by $\text{sol}(N)$.

Example 2. Let $N = (X, D, C)$ be a network with $X = (x_1, x_2, x_3, x_4)$, $D(x_i) = \{1, 2, 3, 4, 5\}$ for all $i \in [1..4]$ and $C = \{c_1(x_1, x_2, x_3), c_2(x_1, x_2, x_3), c_3(x_2, x_4)\}$ with $c_1(x_1, x_2, x_3) = \text{alldifferent}(x_1, x_2, x_3)$, $c_2(x_1, x_2, x_3) \equiv (x_1 \leq x_2 \leq x_3)$, and $c_3(x_2, x_4) \equiv (x_4 \geq 2 \cdot x_2)$. $I_1 = ((x_1, 1), (x_2, 2), (x_4, 7))$ is a nonvalid instantiation on $Y = (x_1, x_2, x_4)$ because $7 \notin D(x_4)$. $I_2 = ((x_1, 1), (x_2, 1), (x_4, 3))$ is a locally consistent instantiation on Y because c_3 is the only constraint with scheme included in Y and it is satisfied by $I_2[X(c_3)]$. $I_3 = ((x_1, 1), (x_2, 2), (x_3, 3), (x_4, 5))$ is a solution because it is a locally consistent instantiation on X .

ARC CONSISTENCY

Arc consistency is the oldest and most well-known way of propagating constraints. This is indeed a very simple and natural concept that guarantees every value in a domain to be consistent with every constraint.

Example 3 [From Ref. 2]. Let N be the network that involves the three variables x_1 , x_2 , and x_3 , domains $D(x_1) = D(x_2) = D(x_3) = \{1, 2, 3\}$, and constraints $c_{12} \equiv (x_1 = x_2)$ and $c_{23} \equiv (x_2 < x_3)$. N is not arc consistent because there are some values inconsistent with some constraints. Checking constraint c_{12} does not permit to remove any value. But when checking constraint c_{23} , we see that $(x_2, 3)$ must be removed because there is no value greater than it in $D(x_3)$. We can also remove value 1

from $D(x_3)$ because of constraint c_{23} . Removing 3 from $D(x_2)$ causes in turn the removal of value 3 for x_1 because of constraint c_{12} . Now, all remaining values are compatible with all constraints.

The seminal papers on arc consistency are due to Mackworth, who was the first to clearly define the concept of arc consistency for binary constraints [3], extend definitions and algorithms to nonbinary constraints [4], and analyze the complexity [5].

I give a definition of arc consistency in its most general form, that is, for arbitrary constraint networks. In this case it is often called *generalized arc consistency* (GAC).

Definition 4 [(Generalized) arc consistency ((G)AC)]. Given a network $N = (X, D, C)$, a constraint $c \in C$, and a variable $x_i \in X(c)$,

- A value $v_i \in D(x_i)$ is *consistent with c* in D iff there exists a valid tuple τ satisfying c such that $v_i = \tau[\{x_i\}]$. Such a tuple is called a *support* for (x_i, v_i) on c .
- The constraint c is (generalized) arc consistent on D iff all values of all variables in $X(c)$ have a support on c .
- The network N is (generalized) arc consistent iff all constraints in C are (generalized) arc consistent on D .

By achieving (or enforcing) arc consistency on a network $N = (X, D, C)$, I mean finding the *arc consistent closure* $AC(N)$ of N . $AC(N)$ is the network (X, D_{AC}, C) where $D_{AC} = \cup\{D' \subseteq D \mid (X, D', C) \text{ is arc consistent}\}$. $AC(N)$ is arc consistent and is *unique*. It has the same solutions as N .

Enforcing Arc Consistency

Proposing efficient algorithms for enforcing arc consistency has always been considered as a central question in the constraint reasoning community. A first reason is that arc consistency is the basic propagation mechanism that is used in all solvers. A second reason is that the new ideas that permit to improve

efficiency of arc consistency can usually be applied to algorithms achieving other local consistencies.

The most well-known algorithm for arc consistency is the one proposed by Mackworth in Ref. 3 under the name AC3. It was extended to GAC in arbitrary networks in Ref. 4. I present it in its general version. (See Algorithm 1.)

The main component of GAC3 is the revision of an arc, that is, the update of a domain with respect to a constraint. (The word “arc” comes from the binary case but we also use it on nonbinary constraints.) Updating a domain $D(x_i)$ with respect to a constraint c means removing every value in $D(x_i)$ that is not consistent with c . The function $\text{Revise}(x_i, c)$ takes each value v_i in $D(x_i)$ in turn (line 2), and explores the space $D^{X(c) \setminus \{x_i\}}$, looking for a support on c for v_i (line 3). If such a support is not found, v_i is removed from $D(x_i)$ and the fact that $D(x_i)$ has been changed is flagged (lines 4–5). The function returns true if the domain $D(x_i)$ has been reduced, false otherwise (line 6).

The main algorithm is a simple loop that revises the arcs until no change occurs, to ensure that all domains are consistent with all constraints. To avoid too many useless calls to Revise , the algorithm maintains a list Q of all the pairs (x_i, c) for which we are not sure that $D(x_i)$ is arc consistent on c . In line 7, Q is filled with all possible pairs (x_i, c) such that $x_i \in X(c)$. Then, the main loop (line 8) picks the pairs (x_i, c) in Q one by one (line 9) and calls $\text{Revise}(x_i, c)$ (line 10). If $D(x_i)$ is wiped out, the algorithm returns false (line 11). Otherwise, if $D(x_i)$ is modified, it can be the case that a value for another variable x_j has lost its support on a constraint c' involving both x_i and x_j . Hence, all pairs (x_j, c') such that $x_i, x_j \in X(c')$ must be put again in Q (line 12). When Q is empty, the algorithm returns true (line 13) as we are sure that all arcs have been revised and all remaining values of all variables are consistent with all constraints.

Algorithm 1: AC3 / GAC3

```

function Revise3(in  $x_i$ : variable;  $c$ : constraint): Boolean;
  begin
    1  CHANGE  $\leftarrow$  false;
    2  foreach  $v_i \in D(x_i)$  do
    3    if  $\nexists$  a valid tuple  $\tau \in c$  with  $\tau[x_i] = v_i$  then
    4      remove  $v_i$  from  $D(x_i)$ ;
    5      CHANGE  $\leftarrow$  true;
    6  return CHANGE;
  end

function AC3/GAC3(in  $X$ : set): Boolean;
  begin
    /* initialisation */;
    7   $Q \leftarrow \{(x_i, c) \mid c \in C, x_i \in X(c)\}$ ;
    /* propagation */;
    8  while  $Q \neq \emptyset$  do
    9    select and remove  $(x_i, c)$  from  $Q$ ;
    10   if Revise( $x_i, c$ ) then
    11     if  $D(x_i) = \emptyset$  then return false;
    12     else  $Q \leftarrow Q \cup \{(x_j, c') \mid c' \in C \wedge c' \neq c \wedge x_i, x_j \in X(c') \wedge j \neq i\}$ ;
    13 return true;
  end

```

GAC3 is polynomial in the arity of the constraints. It runs in $O(er^3 d^{r+1})$ time, where r is the greatest arity among constraints. When constraints are all binary, this gives $O(ed^3)$ time. The time complexity of AC3 is not optimal. The fact that function Revise does not remember anything about its computations to find supports for values leads AC3 to do and redo many times the same constraint checks.

A lot of work has been done to improve the worst-case time complexity of AC3. Mohr and Henderson proposed AC4, the first optimal algorithm for arc consistency ($O(ed^2)$ on binary constraints and $O(erd^r)$ in general), at the price of heavy data structures [6,7]. Bessiere and Cordier proposed AC6, a compromise between AC3 and AC4 that maintains a subtle data structure of lists that have appeared to be difficult to integrate in standard constraint solvers [8,9]. Bessiere, Régim, Yap, and Zhang proposed AC2001, which has the advantage of being based on the same framework as AC3 while having optimal time complexity, like AC4 and AC6 [10]. Finally, Lecoutre and Hemery have proposed AC3rm, an algorithm particularly

efficient for maintaining arc consistency during search [11]. AC3rm stores information in a way similar to AC2001, uses the concept of multidirectionality as AC7 does [12], but does not restore information when backtracking to previous states of search. AC3rm thus loses the theoretical time optimality of the algorithms on which it is based but it works well in practice. Several modern constraint solvers are based on ACrm.

CONSISTENCIES STRONGER THAN ARC CONSISTENCY

Arc consistency is not the only way to detect inconsistencies in a network, and as early as in the 1970s, several authors proposed techniques that discover more inconsistencies than arc consistency. Freuder extended the notion of local consistency to a whole class of consistencies stronger than arc consistency, called k -consistencies [13,14]. Enforcing k -consistency makes explicit nogoods of size $k - 1$.

Definition 5 [k -consistency]. Let $N = (X, D, C)$ be a network.

Given a set of variables $Y \subseteq X$ with $|Y| = k - 1$, a locally consistent instantiation I on Y is k -consistent iff for any k th variable $x_{i_k} \in X \setminus Y$ there exists a value $v_{i_k} \in D(x_{i_k})$ such that $I \cup \{(x_{i_k}, v_{i_k})\}$ is locally consistent.

The network N is k -consistent iff for any set Y of $k - 1$ variables, any locally consistent instantiation on Y is k -consistent.

Before Freuder proposed k -consistency, Montanari had proposed a local consistency called *path consistency*. It was defined for binary networks where each pair of variables is involved in at most one constraint [15]. In such networks, path consistency is equivalent to 3-consistency.

Example 4. Consider the network N with variables x_1, x_2, x_3 , domains $D(x_1) = D(x_2) = D(x_3) = \{1, 2\}$, and $C = \{x_1 \neq x_2, x_2 \neq x_3\}$. The pairs $((x_1, 1), (x_3, 2))$ and $((x_1, 2), (x_3, 1))$ are locally consistent because no constraint has its scope included in $\{x_1, x_3\}$, but they cannot be extended to a value of x_2 satisfying both $x_1 \neq x_2$ and $x_2 \neq x_3$. Thus, N is not path/3-consistent. The network $N' = (X, D, C \cup \{x_1 = x_3\})$ is path/3-consistent.

Freuder also defined strong k -consistencies. They are properties that guarantee that the network is j -consistent for $1 \leq j \leq k$. Thus, we can build from scratch a locally consistent instantiation of size k without any backtrack.

Definition 6 [Strong k -consistency]. A network is *strongly k -consistent* iff it is j -consistent for all $j \leq k$.

The maximal amount of simplification we can perform on a network is to reach a network on which *all* locally consistent instantiations can be extended to solutions. Strong n -consistency guarantees that, with $|X| = n$.

A drawback of k -consistency is that enforcing it will produce additional constraints of arity $k - 1$ that were not in C_N

(see Example 4) and that are expensive to store. In Ref. 16, Freuder proposed (i, j) -consistency, a generalization of k -consistency where we do not guarantee that instantiations of size $k - 1$ can be extended to instantiations of size k , but instantiations of size i can be extended to j additional variables. k -consistency is $(k - 1, 1)$ -consistency. Since the main drawback of k -consistencies is the huge space they require to store all forbidden instantiations of size $k - 1$, we can design local consistencies requiring less space by setting i to a small value in (i, j) -consistency.

Consistencies based on Constraints

All strong consistencies we have seen until now are properties of partial instantiations of variables with respect to other variables. They do not take into account the network topology, that is, which sets of variables are linked by a constraint and which are not. This is a limitation for constraint propagation, which creates new constraints everywhere in the network.

Janssen *et al.* proposed a first local consistency based on constraints instead of variables [17]. It was applied from works on relational databases [18].

Definition 7 [Pairwise consistency].

Given a network N , a pair of constraints c_1 and c_2 in C_N is pairwise consistent iff any valid tuple on $X(c_1)$ (respectively, on $X(c_2)$) satisfying c_1 (respectively, c_2) can be extended to a valid instantiation on $X(c_1) \cup X(c_2)$ satisfying c_2 (respectively, c_1). N is *pairwise consistent* iff any pair of constraints in C_N is pairwise consistent.

Example 5. Consider the network with variables x_1, x_2, x_3, x_4 , domains $D(x_1) = D(x_2) = D(x_3) = D(x_4) = \{1, 2\}$ and constraints $c_1(x_1, x_2, x_3) = \{(1, 2, 1), (2, 1, 1), (2, 2, 2)\}$ and $c_2(x_2, x_3, x_4) = \{(1, 1, 1), (2, 2, 2)\}$. This network is generalized arc consistent. However, it is not pairwise consistent because the tuple $(1, 2, 1)$ from c_1 is not compatible with any tuple in c_2 .

Janssen *et al.* showed in Ref. 17 that pairwise consistency is equivalent to 2-consistency on the dual encoding of the

network, where dual variables represent constraints of the original network [19].

Other authors proposed other types of consistencies, that, like k -consistency, can be defined for arbitrary levels. In a database context, Gyssens proposed k -wise consistency, a direct extension of pairwise consistency where we consider k constraints at a time instead of two [20]. Jégou applied this notion to constraint networks [21]. In Ref. 22, Jégou proposed another duality between variables and constraints. He presents hyper k -consistency.

Dechter and van Beek proposed a new form of local consistency which is more bound to schemes of constraints already in the network than hyper k -consistency is. They refer to those new types of consistencies as *relational* consistencies [23].

Definition 8 [Relational (i, m) -consistency]. Let N be a network. A set of constraints $\{c_1, \dots, c_m\} \subseteq C_N$ is relationally (i, m) -consistent iff for every subset of variables $Y \subseteq \bigcup_{i=1}^m X(c_i)$ such that $|Y| = i$, any locally consistent instantiation on Y has an extension to $\bigcup_{i=1}^m X(c_i)$ that satisfies $c_1, \dots, c_m$ simultaneously. N is relationally (i, m) -consistent iff every subset of m constraints in C_N is relationally (i, m) -consistent.

GAC is relational $(1, 1)$ -consistency.

Consistencies that only Prune Values

There exist local consistencies that permit to prune more values than arc consistency while keeping the set of constraints unchanged (as opposed to what is done by k -consistencies and consistencies based on constraints). Several of them are different kinds of reasoning we can apply on triples of variables. Examples are restricted path consistency (RPC) [24], path-inverse consistent (PIC) [25], or max-restricted path consistency (maxRPC) [26].

Another approach to enhance the amount of values pruned consists in trying in turn different assignments of a value to a variable, and performing constraint propagation on the subproblem obtained by this assignment.

If the problem is found to be inconsistent, this means that this value does not belong to any solution and thus can be pruned. This kind of technique was used on the bounds of interval domains in scheduling (“shaving” in Ref. 27) or on continuous CSPs (3B-consistency in Ref. 28). This technique was also used on Boolean variables as a way to derive better variable ordering heuristics in search procedures for formulas in conjunctive normal form (SAT) in Refs 29 and 30. Finally, it was formalized as a class of local consistencies in Refs 31–33 under the name “singleton consistencies.” I give the definition in the case where the amount of propagation applied to each subproblem is arc consistency. In the following, the subnetwork obtained from a network N by reducing the domain of a variable x_i to the singleton $\{v_i\}$ is denoted by $N|_{x_i=v_i}$.

Definition 9 [Singleton arc consistency]. A network $N = (X, D, C)$ is *singleton arc consistent* (SAC) iff for all $x_i \in X$, for all $v_i \in D(x_i)$, the subproblem $N|_{x_i=v_i}$ can be made arc consistent without wiping out a domain.

Several algorithms have been proposed for establishing SAC [31, 34–36].

CONSISTENCIES WEAKER THAN ARC CONSISTENCY

When constraints involve a great number of variables, even arc consistency can become too expensive to be applied at each node of a backtrack search. We can use the fact that domains are composed of integers to perform cheaper propagation. Integer domains inherit the total ordering on z and by consequence they inherit the smallest and greatest values in $D(x_i)$, denoted by $\min_D(x_i)$ and $\max_D(x_i)$ respectively, and called the *bounds* of $D(x_i)$. Bound consistency is a local consistency that uses the ordering on the domains to reduce the cost of propagating a constraint. (It is called BC(Z) in Refs 2 and 37.)

Definition 10 [Bound consistency]. Given a network $N = (X, D, C)$, given a constraint c , a *bound support* τ on c is

a tuple that satisfies c and such that for all $x_i \in X(c)$, $\min_D(x_i) \leq \tau[x_i] \leq \max_D(x_i)$. A constraint c is *bound consistent (BC)* iff for all $x_i \in X(c)$, $(x_i, \min_D(x_i))$ and $(x_i, \max_D(x_i))$ belong to a bound support on c . The network N is bound consistent iff all its constraints are bound consistent.

Example 6 [From Ref. 2]. Consider the network with variables $x_1, \dots, x_6$, domains $D(x_1) = D(x_2) = \{1, 2\}$, $D(x_3) = D(x_4) = \{2, 3, 5, 6\}$, $D(x_5) = \{5\}$, $D(x_6) = [3..7]$, and $C = \{\text{alldifferent}(x_1 \dots, x_6)\}$. BC will only prune value 2 from $D(x_3)$ and $D(x_4)$ because they are the only bounds for which we cannot find a bound support. GAC will additionally prune value 5 from $D(x_3)$ and $D(x_4)$ and values 3, 5, and 6 from $D(x_6)$.

CONSTRAINT PROPAGATION AS ITERATION OF REDUCTION RULES

In previous sections, I presented local consistencies in a generic way without saying what should be done when we have some specific information on the semantics of a constraint. In constraint solvers, many specific constraints are already defined. For these constraints, it is often very inefficient to call a generic propagation algorithm such as the function *Revise* in Algorithm 1. Hence, these solvers attach a specific propagator to the specific types of constraints they contain. The simplest way of designing a propagator is to specify a set of propagation rules. A propagation rule is a condition under which some values can be pruned. The propagation algorithm iterates on the rules until no more changes occur in domains, that is, until a fixpoint has been reached. This rules iteration process may achieve a given level of local consistency or may reach a fixpoint that does not correspond to any properly defined level of consistency. I will just illustrate propagation rules through an example. The full theory on rules iteration can be found in Refs 38–42.

Example 7. Consider the constraint $\text{alldifferent}(x, y, z)$. Instead of calling the

function *Revise* to propagate this constraint, which would cost $O(d^3)$, we can build the following three rules:

- R1: **if** $\exists v, D(x) = \{v\}$ **then** remove v from $D(y)$ and $D(z)$
- R2: **if** $\exists v, D(y) = \{v\}$ **then** remove v from $D(x)$ and $D(z)$
- R3: **if** $\exists v, D(z) = \{v\}$ **then** remove v from $D(x)$ and $D(y)$

We see that this set of rules is very time efficient because it is constant time to apply it each time a domain has been modified. However, it does not achieve arc consistency. Suppose $D(x) = D(y) = \{1, 2\}$ and $D(z) = \{1, 2, 3, 4\}$, these rules do not prune Anything, whereas 1 and 2 would be pruned from $D(z)$ by arc consistency.

Constraint solvers usually provide other facilities to improve the efficiency of propagation. Arithmetic constraints are at the core of most constraint solvers and it appears that when considering arithmetic constraints, a reduction of a domain does not produce the same effect on the other variables of the constraint, depending on if it is the removal of a value in the middle of the domain, if it is the increase of its minimum value, if it is the decrease of its maximum value, or if it is an instantiation to a single value. Then, it is worth differentiating these different types of *events* to be able to propagate exactly as necessary. The events usually recognized by constraint solvers are:

- $\text{RemValue}(x_i)$: when a value v is removed from $D(x_i)$
- $\text{IncMin}(x_i)$: when the minimum value of $D(x_i)$ increases
- $\text{DecMax}(x_i)$: when the maximum value of $D(x_i)$ decreases
- $\text{Instantiate}(x_i)$: when $D(x_i)$ becomes a singleton

With such a differentiation of events, the rule **R3** in the constraint of Example 7 will be put in the list of rules to be woken only when the event $\text{Instantiate}(z)$ is set to true. For instance, if 1 and 3 are removed from $D(z) =$

$\{1, 2, 3, 4\}$, only $\text{RemValue}(z)$ and $\text{IncMin}(z)$ are set to true, thus no rule from constraint $\text{alldifferent}(x, y, z)$ is put in the propagation list. If 1, 2, and 3 are removed from $D(z) = \{1, 2, 3, 4\}$, $\text{Instantiate}(z)$ is set to true. As a result, rule **R3** is put in the propagation list to be woken.

I have briefly presented the basics of what is common to most solvers. However, the art of designing constraint propagators is not a mature science yet, and things can differ from one solver to another. More information can be found in academic publications [43–48] and in manuals of constraint solvers (see also Chapter 14 in Part II of Ref. 49).

GLOBAL CONSTRAINTS

There are “constraint patterns” that are ubiquitous when trying to express real problems as constraint networks. For example, we often need to say that a set of variables must all take different values. The size of the pattern is not fixed, that is, there can be any number of variables in the set. The alldifferent constraint, as introduced in CHIP [50], is not a single constraint but a whole class of constraints. Any constraint specifying that its variables must all take different values is an alldifferent constraint. The conventional wisdom is to name “global constraints” these classes of constraints that are defined by a Boolean function whose domain contains tuples of values of any length. An instance c of a given global constraint is a constraint with a fixed scheme of variables which contains all tuples of length $|X(c)|$ accepted by the function defining the global constraint. Beldiceanu *et al.* proposed an extensive list of global constraints [51].

Example 8. The $\text{alldifferent}(x_1, \dots, x_n)$ global constraint is the class of constraints that are defined on any sequence of n variables, $n \geq 2$, such that $x_i \neq x_j$ for all $i, j, 1 \leq i, j \leq n, i \neq j$. The $\text{NValue}(y, [x_1, \dots, x_n])$ global constraint is the class of constraints that are defined on any sequence of $n + 1$ variables, $n \geq 1$, such that the number of distinct values taken by $[x_1, \dots, x_n]$ must be equal to y , that is, $|\{x_i | 1 \leq i \leq n\}| = y$ [52, 53].

It is interesting to incorporate global constraints in constraint solvers so that users can use them to express the corresponding constraint pattern easily. Because these global constraints can be used with a scheme of any size, it is important to have a way to propagate them without using generic arc consistency algorithms. (Remember that optimal generic arc consistency algorithms are in $O(erd^r)$ for constraints involving r variables—see the section titled “Arc Consistency.”)

The first alternative to the combinatorial explosion of generic algorithms for GAC on a global constraint is to decompose it with “simpler” constraints. A *decomposition* of a global constraint G is a *polynomial time* transformation δ_k (k being an integer) that, given any network $N = (X(c), D, \{c\})$ where c is an instance of G , returns a network $\delta_k(N)$ such that $X(c) \subseteq X_{\delta_k(N)}$, $D(x_i) = D_{\delta_k(N)}(x_i)$ for all $x_i \in X(c)$, $|X(c_j)| \leq k$ for all $c_j \in \bar{C}_{\delta_k(N)}$, and $\text{sol}(N)$ is equal to the projection of $\text{sol}(\delta_k(N))$ on $X(c)$. That is, transforming N in $\delta_k(N)$ means replacing c by some new bounded arity constraints (and possibly new variables), whereas preserving the set of tuples allowed on $X(c)$. Note that by definition, the domains of the additional variables in the decomposition are necessarily of polynomial size.

Example 9. The global constraint $\text{atmost}_{p,v}(x_1, \dots, x_n)$ holds if and only if at most p variables in $x_1, \dots, x_n$ take value v [54]. This constraint can be decomposed with $n + 1$ additional variables $y_0, \dots, y_n$. The transformation involves the constraint $(x_i = v \wedge y_i = y_{i-1} + 1) \vee (x_i \neq v \wedge y_i = y_{i-1})$ for all $i, 1 \leq i \leq n$, and the domains $D(y_0) = \{0\}$ and $D(y_i) = \{0, \dots, p\}$ for all $i, 1 \leq i \leq n$.

It is desirable to design decompositions that *preserve* GAC on the original global constraint. That is, given any instance c of a global constraint G and any initial domain D on $X(c)$, given the corresponding decomposition, we want that for any domain included in D , GAC applied on the decomposition prunes exactly the same values as GAC on c . $\text{atmost}_{p,v}$ is a global constraint

that admits a decomposition preserving GAC (see Example 9).

Unfortunately, it is not always possible to find a decomposition preserving GAC. In Ref. 55, Bessiere *et al.* use tools of computational complexity to decide when a given global constraint has no chance to allow a decomposition preserving GAC. If enforcing GAC on a global constraint G is NP-hard, there does not exist any decomposition that preserves GAC (assuming $P \neq NP$). For instance, enforcing GAC on NValue is NP-hard. This tells us that there is no way to find a decomposition on which GAC always removes all GAC inconsistent values of the original NValue constraint.

Recently, Bessiere *et al.* have shown that NP-hard constraints are not the only class of global constraints for which no decompositions preserving GAC exist. They used circuit complexity theory to show that if a global constraint expresses a pattern that cannot be encoded as a monotone circuit of polynomial size then it cannot be decomposed even if it is not NP-hard to enforce GAC on it [56]. A famous example is the alldifferent constraint. For those constraints, the solution is to build a specialized algorithm that enforces GAC in polynomial time. For instance, there is a strong relationship between GAC on the alldifferent constraint and the problem of finding maximal matchings in a bipartite graph [57,58]. This relationship was used by Régim to propose a polynomial algorithm for GAC on the alldifferent constraint.

BASIC CP THEORY: SEARCH

LAURENT MICHEL
Computer Science and Engineering,
University of Connecticut, Storrs,
Connecticut

PASCAL VAN HENTENRYCK
Computer Science, Brown University,
Providence, Rhode Island

Constraint programming (CP) has, from its inception, adhered to the following basic tenet

$$\text{CP} = \text{Modeling} + \text{Search},$$

which puts as much emphasis on the ability to specify how to explore the search space as it does on how to model the constraints that any solution must satisfy. Separating the constraint model from the search fosters good modeling practices where one can extend the model with little to no concern for the search and vice versa. Indeed, the addition of new constraints should not force users to reconsider their search to exploit the enhancements. The benefits ought to be transparent. Specifying the search proves instrumental when facing hard problems where one wishes to exploit the semantics of the application to engineer a search procedure that is more effective.

Operations research practitioners well versed in mathematical optimization are accustomed to the idea of developing solutions almost exclusively through modeling. The extent of the control they can exercise on the solution process is through a selection of high level parameters for the solver at hand (e.g., the many parameters of the CPLEX solver). CP offers a different perspective on this issue, and its flexibility and ability to deal with hard problems often stems from sophisticated search procedures that exploit semantics of the problems that are hard or near impossible to model through traditional constraints. The most resounding success stories in scheduling [1], bounded program and model verification [2,3], distributed

system deployment [4], test generation [5], and sport scheduling [6–8], to name just a few, invariably take advantage of the ability to specify the search.

While *black-box* search procedures are undeniably desirable, as they offer a first generic search option that can work without further ado, retaining the key advantage to replace these generic procedures with user-defined ones is critical. The fundamental design challenge for CP languages and toolkits is to enable the specification of a user-definable search procedure while striking the right balance between three conflicting objectives, namely:

1. The clarity of the specification,
2. The flexibility of the specification to accommodate arbitrary levels of control, and
3. The efficiency of the resulting search.

The purpose of this article is to offer insights into what a CP search does, how orthogonal aspects of the search can be clearly and easily specified, and hint at how the underlying engines achieve this result. For clarity's sake, the article illustrates all the ideas with the COMET optimization platform [9,10], as it offers a simple, versatile, and yet powerful search specification language.

The rest of this article is organized as follows. The section titled “Fundamentals” presents the computational model underlying the execution of a search procedure. It presents, at a high level, how the constraint propagation meshes with the search process and provides a simple semantics for what goes on during the search. The section titled “Driving Example: The Steel Mill Slab” presents the driving example that will be used throughout the article. The section titled “Heuristics” introduces the notion of heuristics and how they shape the search tree that embodies the entire search space. The section titled “Strategies” discusses the role of strategies, that is, how to explore the search tree induced by

the heuristics. The section titled “Meta Strategies” touches on metastrategies, that is, the means to alter the overall behavior of the search process through techniques like randomization, restarts [11], or large neighborhood search (LDS) [12]. Finally, the last section concludes the article.

FUNDAMENTALS

CP is typically used to solve *constraint satisfaction problems* (CSP for short) specified with a triplet $P = \langle X, D, C \rangle$ where X is the set of decision variables, D_i is the domain of variable $x_i \in X$ (a finite set of discrete values, typically the integers), and C is a set of constraints over variables from X . $\text{vars}(c)$ denotes the subset of variables from X that appear in constraint c while $|\text{vars}(c)|$ is the arity of c .

Definition 1 [Infeasibility]. A CSP $P = \langle X, D, C \rangle$ is *failed* (*failed*(P)) if and only if $\exists x_i \in X$ s.t. $D_i = \emptyset$.

Definition 2 [Solution]. A CSP $P = \langle X, D, C \rangle$ is *solved* (*solved*(P)) if and only if $\forall x_i \in X : |D_i| = 1$ and C is true with respect to D .

Definition 3 [Solution set]. The solution set of $P = \langle X, D, C \rangle$, written $S(P)$, is $\{T = \langle X, [\{s_0\}, \{s_1\}, \dots, \{s_{n-1}\}], C \rangle$ s.t. $s_0 \in D_0 \wedge s_1 \in D_1 \wedge \dots \wedge s_{n-1} \in D_{n-1} \wedge \text{solved}(T)\}$ (where $|X| = n$).

CP can also accommodate *constraint optimization problems* (COP for short) where an additional objective function $f : X \rightarrow \mathbb{N}$ provides a quality measure for any solution. Optimization problems are, however, dealt with via a reduction back to satisfaction problems. Indeed, a COP $\langle X, D, C, f \rangle$ can first be turned into a CSP $\langle X, D, C \rangle$. A search for all the solutions of this CSP would yield a sequence of solutions $(s_0, f_0), \dots$, where f_0 denotes the value of the function f in s_0 . Given s_0 , one can easily produce and solve a subsequent CSP $\langle X, D, C \cup \{f < f_0\} \rangle$. This new CSP is either infeasible, in which case s_0 is guaranteed to be a global optimum, or it will deliver a solution (s_1, f_1) . The process can be repeated until the k th CSP

becomes infeasible and the process delivers the global optimum s_{k-1} . Therefore, and without loss of generality, the rest of the article focuses exclusively on constraint satisfaction.

Constraint Propagation

As discussed in the article titled *Basic CP Theory: Consistency and Propagation (Advanced)* in this encyclopedia, constraint propagation is a contraction operation which, given a CSP $\langle X, D, C \rangle$, yields new domains D' such that $\forall x_i \in X : D'_i \subseteq D_i$. The contraction is achieved by enforcing a local consistency property on the variables. Generalized arc-consistency (GAC) [13–15] is the most prevalent type of consistency and can be expressed as follows: The CSP $\langle X, D, C \rangle$ is GAC if and only if every constraint $c \in C$ is GAC. A constraint c (of arity k) is GAC if and only if it is GAC with respect to all its variables. Finally, c is GAC with respect to variable $x_j \in \text{vars}(c)$ if and only if

$$\forall v \in D_j, \exists w_0 \in D_0, \exists w_1 \in D_1, \dots, \exists w_{k-1} \in D_{k-1} : c(w_0, w_1, \dots, w_{j-1}, v, w_{j+1}, \dots, w_{k-1}).$$

The prune algorithm uses the GAC definition to eliminate values from D_j that cannot appear in a solution tuple to the constraint c . This contraction process can have three outcomes. First, the contraction can yield new domains D' such that *failed*($\langle X, D', C \rangle$) is true. An empty domain is a manifestation of an inconsistent constraint set. Second, the contraction can yield new domains D' satisfying *solved*($\langle X, D', C \rangle$), in which case the propagation has produced a solution. Finally, the contraction can yield new domains D' where at least one variable has two or more values left in its domain, which indicates that the propagation is inconclusive and the CSP could have zero, one, or more solutions.

Decomposition

When the propagation is inconclusive, it becomes necessary to *branch* to decompose the instance into smaller instances for which the propagation might be able to determine

if the outcome is infeasible, a solution, or in need of further decomposition.

Definition 4 [Branching]. A branching decision is a sequence of k ($k \geq 2$) constraints $[c_0, \dots, c_{k-1}]$ that decomposes a CSP instance $P = \langle X, D, C \rangle$ into k subinstances $P_{j \in 0..k-1} = \langle X, D, C \cup \{c_j\} \rangle$ forming a partition, that is, no solutions are lost: $S(P) = \bigcup_{i=0}^{k-1} S(P_i)$, and the subinstances are nonoverlapping $\forall i, j \in 0..k-1, i \neq j : S(P_i) \cap S(P_j) = \emptyset$.

Example 1 [Binary Branching]. A very simple branching decision is $[x = v, x \neq v]$. Indeed, Given $P = \langle X, D, C \rangle$ and $[x = v, x \neq v]$ for $x \in X$ and $v \in D(x)$, one easily derives $P_0 = \langle X, D, C \cup \{x = v\} \rangle$ and $P_1 = \langle X, D, C \cup \{x \neq v\} \rangle$. The two problems yield a partition as all solutions must have their x either equal to v or different from it. It also yields a nonoverlapping partition since a solution cannot simultaneously satisfy $x = v$ and $x \neq v$.

Once an instance is decomposed, the propagation algorithm (prune) is applied to each subinstance to further contract the domains and eliminate the values that are no longer consistent.

Search Tree

Given a propagation algorithm and a decomposition scheme, it is possible to define a search tree.

Definition 5 [Search Tree]. A search tree for a CSP $P = \langle X, D, C \rangle$ is an ordered k -ary tree rooted at P and defined inductively as follows:

$$tree(P) = failNode(P) \Leftrightarrow failed(P)$$

$$tree(P) = solNode(P) \Leftrightarrow solved(P)$$

$$tree(P) = intNode([P_0, P_1, \dots, P_{k-1}]) \Leftrightarrow$$

$$\begin{cases} \neg failed(P) \wedge \\ \neg solved(P) \wedge \\ branching(P) = [c_0, \dots, c_{k-1}] \wedge \\ \forall i \in 0..k-1 : P_i = \langle X, D, C \cup \{c_i\} \rangle, \end{cases}$$

where $failNode(P)$ and $solNode(P)$ denote leaves of the tree and $intNode([P_0, \dots, P_{k-1}])$ is an internal node. A pictorial representation is shown in Fig. 1. The ordered tree $tree(P)$ is a by-product of the initial CSP and the branching rules (which produces the branching decisions) in effect. Clearly, the branching rule can inspect the CSP P to produce a suitable branching decision (i.e., an ordered sequence of constraints).

Figure 1. Search tree.

The topology of the tree depends directly on the branching decision which is commonly known as the *variable/value selection* heuristic. The search tree, when rooted at P , structures the entire search space to facilitate the search process per se.

Search Strategy

Given a search tree T for a CSP $P = \langle X, D, C \rangle$, a search *algorithm* carries out the exhaustive exploration of T . The exploration can adopt a traditional technique like depth-first search where the algorithm always first expand the leftmost nonvisited node of the tree recommended by the heuristic. However, the tree exploration is not limited to this *strategy*. Instead, it could elect to first expand any other nonvisited node currently present in the “fringe” (unexpanded region) of the tree.

Richer options include best-first search, limited discrepancy search (LDS), or iterative deepening to name just a few. The motivation to select one strategy or another is intimately linked with the effectiveness of the branching decision. Indeed, if an oracle is available as a branching decision, it will always produce an ordering of the branching constraints that places the solution of the problem on a leftmost path in the search tree, in which case a simple depth-first strategy is perfect. On the other hand, if the branching heuristic is weaker, a more sophisticated node selection strategy can compensate by exploring paths that are distributed throughout the search tree and jump from one node of the fringe to another as the expansions proceed. It could also recognize that the latest failure it encountered is caused by one or more decisions (known as *nogoods* [16]) that were made at shallower depths in the search and jump back over several branching decisions that are not causally related to reconsider what caused the failure. The finding of nogoods can occur prior to the search [17], but more importantly, it can happen dynamically as the search proceeds [18–20]. Nonchronological strategies of this type include, for instance, backjumping [16,21] and conflict-directed backjumping [19]. Readers interested

Figure 2. The search procedure.

in a more in-depth account can consult Rossi *et al.* [22].

The search tree that structures the entire search space is never created explicitly. Instead, the search algorithm maintains a subset of its node, the *fringe* (shown in Fig. 1), representing the boundary between examined and unexplored nodes. Initially, the fringe consist of the root of the search tree ($\text{intNode}(P)$). The search algorithm then repeatedly extracts subinstances from the fringe, propagates the instance and, depending on the outcome, it either records a solution (when $\text{solved}(P)$ is true), discards the node (when $\text{failed}(P)$ is true), or decomposes it and adds the newly generated subinstances back into the fringe. The search strategy governs which node is extracted from the fringe, and that decision affects the performance of the search as well as the memory requirements.

The generic search algorithm, shown in Fig. 2, embodies the core of a search procedure. The selection of different *heuristics* and *strategies* translates into an instantiation of the branch and selectAndExtract subroutines, respectively.

CP languages, such as COMET [9], implement this algorithm and provide the necessary mechanism to specify heuristics and strategies with great ease. The COMET specification of the search heuristics is done directly when describing the search tree through two

important control primitives (**try** and **tryall**). The COMET specification of search strategies is achieved via *search controllers* [23,24] that are orthogonal to the search tree specification. Search controllers are responsible for representing and manipulating the fringe.

DRIVING EXAMPLE: THE STEEL MILL SLAB

The search mechanisms at our disposal will be illustrated throughout the paper on an optimization problem known as the *Steel Mill Slab* production problem. The problem is described in Ref. 25, and early CP models were introduced in Ref. 26.

Steel is produced by casting molten iron into slabs. A steel mill can only produce a finite number of slab capacities (lengths). An order has two properties: a color corresponding to the route required through the steel mill, and a length. Given n input orders, the problem is to assign the orders to slabs such that the total size of steel produced is minimized. This assignment is subject to capacity constraints, that is, the total length of orders assigned to a slab cannot exceed the largest slab capacity. It is also subject to coloring constraints, that is, each slab can contain at most two colors. The color constraints arise because it is expensive to cut up slabs in order to send them to different parts of the mill. The basic model is shown in Fig. 3. The

model starts by defining ranges for the customer orders and the steel slabs. It stores in `colorOrder c` the set of orders that require color c . Line 4 stores in `maxCap` the longest slab that can be produced. Line 5 computes the losses one would incur to produce a slab of length at least c , that is, it is the extra length of steel that would be wasted to reach one of the legal capacities. Lines 7–9 define the solver and the decision variables, namely, $x[i]$ denotes the slab number that order i is assigned to and $l[i]$ is the length of the i th steel slab. The model states the objective function on-line 11: minimize the total losses incurred, and the constraints on lines 13–15, namely: define the length l_i of slab i in term of the length of the orders assigned to it and prohibit more than two colors on the same slab. The search specification would appear inside the **using** block starting at line 16.

HEURISTICS

Heuristics control the topology of the search tree and take the form of a sequence of k constraints meant to decompose the CSP instance. This section provide an overview of the major search heuristics and how one can specify them in COMET. Branching heuristics exert their function through two mechanisms, namely, which variable to branch on and in what order values should be considered for the selected variable.

```

1 int nbOrders = sz; range Orders = 1..nbOrders;
2 int nbSlabs = nbOrders; range Slabs = 1..nbSlabs;
3 set{int} colorOrders[c in Colors] = filter (o in Orders) (color[o] == c);
4 int maxCap = max(i in Caps) capacities[i];
5 int loss[c in 0..maxCap] = min(i in Caps: capacities[i] >= c) capacities[i] - c;
6
7 Solver<CP> m();
8 var<CP>{int} x[Orders](m,Slabs);
9 var<CP>{int} l[Slabs](m,0..maxCap);
10
11 minimize<m> sum(s in Slabs) loss[l[s]]
12 subject to {
13     m.post(multiknapsack(x,weight,l));
14     forall(s in Slabs)
15         m.post(sum(c in Colors) (or(o in colorOrders[c]) (x[o] == s)) <= 2);
16 } using...
```

Figure 3. The steel mill slab problem.

The *variable selection heuristic* is responsible for picking the variable to branch on. Many options are possible ranging from a purely static ordering to a completely dynamic ordering (i.e., dependent on which node of the search tree we are currently on). While the generic branching scheme allows for arbitrary branching constraints, all the heuristics in use select a single variable.

The *value selection heuristic* depends upon the class of branching constraints under consideration. Two common schemes exist: *enumeration* and *splitting*.

Enumeration. The most common approach is to enumerate the values in the domain of variable x_i (the chosen variable) by producing a sequence of constraints $[x_i = v_0, x_i = v_1, \dots, x_i = v_{k-1}]$ where the v 's are values from D_i , and the ordering of the values drives the ordering of the branches in the search.

Splitting. A splitting scheme interprets D_i as a range $L_i..U_i$ where L_i and U_i are the smallest (respectively largest) values in D_i and divides the domain in two halves at $(L_i + U_i)/2$ with the branching $[x_i \leq (L_i + U_i)/2, x_i \geq 1 + (L_i + U_i)/2]$. This gives rise to a binary tree where the same variable is considered multiple times at different depths as its domain is repeatedly split.

The variable and the value selection heuristics have at their disposal the current CSP instance and can examine any property to produce their recommendation. This

```

1  ...
2  } using {
3    forall(i in Orders)
4      tryall<m>(v in x[i].getMin()..x[i].getMax() : x[i].memberOf(v))
5        m.post(x[i] == v);
6    cout << x << endl;
7  }
```

At the first iteration of line 3, $i = 1$. The **tryall** instruction on-line 4 picks the first value in $D_1 = \{1..nbSlabs\}$, namely, 1 and posts the constraints $x[1] == 1$ on-line 5. The addition of the constraint triggers a round of propagation. When the propagation ends, the

section first considers *local heuristics* that base their recommendations on information related exclusively to the variable under consideration. The second section focuses on *global heuristics* that assess the effect of a choice on the entire CSP instance. Global heuristics attempt to be less myopic at the expense of significant efforts.

Local Heuristics

The most common heuristics use local information pertaining to variables alone. The heuristics shown below start from the simplest ideas and then increase in sophistication.

Static Ordering. The simplest local heuristic is static ordering. It simply adopts a fixed ordering of the variables and values. Namely, at depth k , the branching will consider variable x_k , as all the variables between depth 0 and depth $k - 1$ have already been fixed. The value selection heuristic at depth k will consider the domain D_k as an ordered set of discrete values (the natural order for the underlying type, that is, $<$ for the integers). The resulting branching decision at depth k is therefore $[x_k = v_0, \dots, x_k = v_{n-1}]$ where $D_k = \{v_0, v_1, \dots, v_{n-1}\}$ is an ordered set of n values, that is, $v_0 < v_1 < \dots < v_{n-1}$.

While static ordering is trivial to specify and implement, it is clearly wholly ignorant of the current state and fails to steer the search in any particular direction. The following fragment illustrates how to specify this heuristic with COMET for the steel mill slab problem.

execution continues and moves to the second iteration of line 3, namely, $i = 2$. Note that other alternatives for $x[1]$ are still available and, should an inconsistency be detected, the search has the option to return to these internal search tree nodes to explore them. In

essence, the **tryall** is a lazy construction that does not expand all the siblings of a node until they are needed by the strategy. Which node to return to depends on the search strategy which will be discussed in the section titled “Strategies.”

```

1 forall(i in Orders : !x[i].bound())
2   tryall<m>(v in x[i].getMin().x[i].getMax() : x[i].memberOf(v))
3     m.post(x[i] == v);

```

Dynamic Variable Ordering. It is often advantageous to branch first on variables with the smallest domains to discover inconsistencies between choices as early as possible. The so-called *min-dom* heuristic

```

1 forall(i in Orders : !x[i].bound()) by (x[i].getSize())
2   tryall<m>(v in x[i].getMin().x[i].getMax() : x[i].memberOf(v))
3     m.post(x[i] == v);

```

implements this idea. Compared to the static ordering, it adds a **by** clause on the **forall** loop that requires the enumeration of the indices i in increasing order of the expression.

Notice how the search above first commits to a variable selection and subsequently attempts to find a value for the variable. The only way to consider another variable is to either successfully impose a constraint on the chosen variables or exhaust all possibilities

```

1 while(!bound(x)) {
2   selectMin(i in Orders : !x[i].bound())(x[i].getSize()) {
3     int v = x[i].getMin();
4     try<m> m.post(x[i] == v);
5       | m.post(x[i] != v);
6   }
7 }

```

embodies this simple idea. The outer loop (line 1) iterates as long as not all the variables in x are bound. The selector on line 2 selects the index i that identifies a free variable with the smallest domain. Line 3 picks the smallest value in its domain and lines 4–5 create a branching decision $[x_i = v, x_i \neq v]$. In case of failure, when the search algorithm selects the second alternative, it imposes

The static ordering shown above can be slightly improved by skipping the variables that may already be bound as a result of propagation. The fragment below illustrates the addition of a predicate on the **forall** loop to only consider variables that are not bound.

embodies the first-fail principle “To succeed, try first where you are most likely to fail” [27]. It is also easy to implement, as it suffices to order the variables according to their domain size. The fragment

and reconsider an earlier node in the search tree (i.e., backtrack to another node). It might be desirable to have a slightly more flexible setup. If the addition of a constraint $x_k == v$ with $v \in D_k$ leads to a failed CSP, the system has learned the negation of the above, namely, $x_k \neq v$. So it might be valuable to impose this new constraint, as its propagation may very well lead to a contraction of domains and a subsequently *better informed* variable selection. The fragment

the $x_i \neq v$ constraint and propagates the constraint system. Therefore, subsequent iterations of the outer loop can pick a different variable for the next choice.

Dynamic Value Ordering. The heuristics considered thus far enumerate the values in the domain of variable x_k in a fixed, static

order (from the smallest to the largest). Note how the ordering of the values impacts the order of the constraints in the branching sequence created at a node of the search tree. While the variable selection controlled the depth at which a variable is fixed, the value selection controls which path lies on the leftmost edge of the search tree.

```

1 forall(i in 1..n : !q[i].bound()) by (q[i].getSize()) {
2   tryall<m>(v in q[i].getMin()..q[i].getMax() : q[i].memberOf(v)) by (abs(v - n/2)) {
3     m.post(q[i] == v);
4   }
5 }

```

illustrates exactly this strategy. The variable selection is still based on the first-fail principle as it first selects the variable with the smallest domain. The value selection heuristic implemented by the ordering clause on the **tryall** instruction on-line 2 orders the value by increasing distance from the middle of the board with the $\text{abs}(v - n/2)$ expression. The use of this heuristic makes it possible to find the first solutions to much larger instances much faster (under 1 s for sizes up to 1024 queens with as few as five failures when the static value ordering cannot get past 128 queens in the same time.)

Degree Ordering. Variable selection based on the smallest domain (i.e., the *min-dom* heuristic) attempts to cause failures early on in the search. The same outcome could be the result of branching on variables that are subjected to many constraints. A first idea is to exploit the *static* or *dynamic* degree (respectively *deg* and *ddeg*) of a variable in the constraint graph. *deg* is the degree of the variable at the root of the search tree, whereas *ddeg* captures the degree during the search (variables that are fixed by branching decisions and/or propagation can be projected out leaving a smaller constraint graph). Intuitively, a variable that appears in many constraints may have a stronger effect than a variable that only appears in a handful of them. Consequently, branching first on variable with maximal degree seems appropriate.

Definition 6 [max-deg]. The most desirable variable to branch on is the

Example 2. Consider the simple problem of placing n queens on an $n \times n$ chess board so that no two queens attack each other. On this problem, the heuristics considered thus far have a tendency to start from a corner of the board. However, it might be advantageous to start from the middle of the board. The fragment

variable which maximizes its static degree *deg* in the constraint graph.

Definition 7 [max-ddeg]. The most desirable variable to branch on is the variable which maximizes its dynamic degree *ddeg* in the constraint graph.

Unsurprisingly, it is also possible to combine *min-dom* with either *max-deg* or *max-ddeg*. These ideas have been proposed to break the ties that appear with *min-dom*.

Definition 8 [dom/deg and dom/ddeg]. The most desirable variable to branch on is the variable which minimizes the ratio domain size over degree (respectively, dynamic degree) [28,29]. Note that lexicographic orderings based on (*min-dom*, *max-deg*) (respectively (*min-dom*, *max-ddeg*)) are also possible.

A further possibility is to take into account the propensity of variables to lead to conflicts. The resulting heuristics, named *wdeg* and *dom/wdeg* [30], are defined as follows:

Definition 9 [w_c]. The weight of constraint c is a nonnegative integer which, during the search, reflects how often the constraint c detected an inconsistency, that is, emptied the domain of one of its variables.

Definition 10 [wdeg]. The weighted degree of variable $x_i \in X$ is defined as

$$wdeg(x_i) = \sum_{c \in C : x_i \in vars(c) \wedge |utVars(c)| > 1} w_c,$$

where $utVars(c) = \{x \in vars(c) \setminus \{x_i\} \text{ s.t. } |D_x| \geq 2\}$, that is, it is the sum of the weights of the constraints that x_i appears in and that have at least one other uninstantiated variable.

Definition 11 [*dom/wdeg*]. The weighted domain heuristic of variable $x_i \in X$ is defined as the ratio $\frac{|D_i|}{wdeg(x_i)}$, that is, the most desirable variable to branch on has the smallest domain and appears in the most conflicting constraints.

The variable selection heuristic can then focus on first selecting the variable with the largest *wdeg* value, as it corresponds to variables appearing in the most constraining part of the CSP. On the other hand, selecting variables with the smallest *dom/wdeg* dictates the selection of variables according to the first-fail principle and tie-breaking according to *wdeg*.

Global Heuristics

Global heuristics attempt to exploit information that is more global to the entire search space in order to make a more informed decision as to which branching decision to make.

Impacts [31]. These are inspired by *pseudo-costs* [32] and strong branching [33] in integer programming which normally measure the effect of a branching decision on the objective function. Here, impacts offer a measure of a constraint effectiveness in reducing the size of the search space. Impacts consider branching constraints of the form $x_i = v$ with $v \in D_i$ which lead to the biggest reduction in the size of the search space.

The core idea of impacts is to estimate the size of the search tree as $P = |D_0| \times |D_1| \times \dots \times |D_{n-1}|$. The impact of a potential branching decision $x_i = v$ can be characterized as

```

1 while(!bound(x)) {
2   selectMin(i in 1..n : !x[i].bound())(variableImpactOf(x[i])) {
3     selectMax(v in x[i].getMin()..x[i].getMax() : x[i].memberOf(v))(assignmentImpactOf(x[i],v)) {
4       try <m> m.post(x[i] == v);
5         | m.post(x[i] != v);
6     }
7 }

```

$$I(x_i = v) = 1 - \frac{P_{\text{after}}}{P_{\text{before}}}.$$

Namely, if the contraction is very strong ($P_{\text{after}} \ll P_{\text{before}}$), the impacts tends toward 1. Refalo [31] observed that, on average, the impact of an assignment tends to be independent of other assignments and proposed maintaining a running average of the impact of $x_i = v$ over the tree nodes that have been treated from the beginning of the search. If K is the set of nodes seen so far, than the impact $\tilde{I}(x_i = v)$ is defined as

$$\tilde{I}(x_i = v) = \frac{\sum_{k \in K} I^k(x_i = v)}{|K|}$$

with $I^k(x_i = v)$ being the impact of the assignment in the tree node k . One can then easily derive a definition for the impact of a variable (regardless of which value it will be constrained to) and use it as a variable selection heuristic. Refalo's derivation in Ref. 31 yields the following definition:

$$\mathcal{I}(x_i) = \sum_{v \in D_i} 1 - \tilde{I}(x_i = v).$$

Observe that if all the values in D_i have high impact (close to 1), then $\mathcal{I}(x_i)$ tends toward 0. Therefore a variable that effectively contracts the search space is one that minimizes $\mathcal{I}(x_i)$. It should be noted that the impacts can easily be produced at the root of the search tree prior to the actual search via a simple preprocessing step. During the search, the running average of the impact of an assignment $x_i = v$ can be updated each time the constraint is considered for branching. The search strategy itself simply uses the variable and value impacts maintained in a global data structure to drive the variable/value selection processes. The fragment

shows the skeleton of an impact-based search (the initialization is omitted). The data structure behind `variableImpactOf` (that returns $\mathcal{I}(x_i)$) and `assignmentImpactOf` (that returns $\tilde{\mathcal{I}}(x_i = v)$) must also be updated each time a constraint is posted.

Singleton Consistency and Look-Aheads. Singleton consistencies [34] (e.g., singleton arc consistency, restricted singleton arc consistency) offer other opportunities to collect data about variables and assignments to derive a global heuristic. The core idea is to slightly enhance the singleton consistency algorithms to collect measurements of the impacts of the assignments being considered. The core idea is to estimate the size of the search tree for a problem P with n variables x_1 through x_n with domains D_1 through D_n as

$$\sigma(P) = \log \left(\prod_{i=1}^n |D_i| \right),$$

or equivalently

$$\sigma(P) = \sum_{i=1}^n \log |D_i|,$$

in which the estimate is the logarithm of the product of the domain sizes. Note the similarity with the impact-based estimation. Refalo's impacts rely on a measurement of the contraction that is derived from a tentative assignment, whereas Correia's measure is a

direct assessment of the tree size (after an assignment), not how it shrinks.

When the singleton consistency algorithm considers the subproblem $P_{|x_i=a} = P \cup \{x_i = a\}$ to decide whether value $a \in D_i$ can or cannot be discarded, it suffices to compute $\sigma(P_{|x_i=a})$ before proceeding to the next value. Once all the values in D_i are examined, the impact of the variable x_i is easily defined as

$$\mathcal{I}(x_i) = \sum_{a \in D_i} \sigma(P_{|x_i=a}).$$

A global variable selection heuristic can then easily be derived given that the variable associated to the smallest $\mathcal{I}(x_i)$ yields the smallest tree to investigate. Note that other variants can be found in Ref. 34. The value selection heuristic is modeled after the same idea. Once again, the best value is a value delivering the largest subtree and thus most likely to lead to a solution. Given a variable selection x_i , it is preferable to pick a value that produces the largest subtree. Therefore, the heuristic is to select the value $a \in D_i$ that maximizes $\max_{a \in D_i} \sigma(P_{|x_i=a})$.

Note that the $SC_d(\mathcal{X}, \mathcal{C})$ and $RSC_d(\mathcal{X}, \mathcal{C})$ routines (as defined in Ref. 34) are easily instrumented to collect the variable and value selection heuristics discussed above. In these routines, the parameter d controls the subset of variables for which the restricted consistency is checked as the set $\{x \in \mathcal{X} \text{ s.t. } |D_x| \leq d\}$. For instance, the fragment

```

1 class SCH {
2   var<CP>{int} theVar;
3   int theVal;
4   float estimate;
5   SCH() { theVar = null; }
6   void update(var<CP>{int} v,int value,float est) {
7     if (theVar==null || est < estimate) {
8       theVar = v;theVal = value;estimate = est;
9     }
10  }
11 }
12 function SCH RSCd(Solver<CP> m,int d) {
13   var<CP>{int}[] vars = m.getIntVariables();
14   SCH best();
15   forall(i in vars.getRange() : !vars[i].bound() && vars[i].getSize() <= d) {
16     Float vh(0);Float mv(0);
17     Integer bv(vars[i].getMin()-1);

```

```

18   forall(a in vars[i].getMin()..vars[i].getMax() : vars[i].memberOf(a)) {
19       bool b = succeeds(m) {
20           m.label(vars[i],a);
21           float ve = sum(i in vars.getRange()) log(vars[i].getSize());
22           vh := vh + ve;
23           mv := max(mv,ve);
24           if (mv == ve) bv := a;
25       };
26       if (!b) m.diff(vars[i],a);
27   }
28   best.update(vars[i],bv,vh);
29 }
30 return best;
31 }

```

is a complete COMET implementation of restricted singleton consistency which returns a tuple with the selected assignment for the next branching decision. The succeeds statement on-line 19 executes the block spanning lines 20 to 25 which does a tentative assignment $x_i = a$ (line 20) and returns true if this was a success and false otherwise. Line 21 computes $\sigma(P_{|x_i=a})$, while line 22 accumulates the sum of the estimates in vh and lines 23–24 track the maximum estimate mv and its corresponding value bv . Line 26 removes the value a from D_i whenever the tentative assignment $x_i = a$ leads to an inconsistency. Note that, if this removal of a from D_i leads to an inconsistency, the backtracking automatically will return to the last choice. The generic search procedure using $RSC_2(\mathcal{X}, \mathcal{C})$ can then be simply defined as

```

1 SCH sel = RSCd(m,2);
2 while (sel!=null) {
3     try <m> m.label(sel.theVar,sel.theVal);
4         | m.diff(sel.theVar,sel.theVal);
5     sel = RSCd(m,2);
6 }

```

Advanced Heuristics. The arsenal of heuristics available to tame hard problems grows regularly and recent advances include heuristics based on estimating the solution densities for constraints in subtrees to decide how to branch [35] or expectation maximization and belief propagation to find likely assignments [36].

```

1 forall(i in 0..n-1)
2     tryall <m> (v in x[i].getMin()..x[i].getMax() : x[i].memberOf(v))
3         m.post(x[i] == v);

```

STRATEGIES

Heuristics attempt to alter the shape of the tree by placing desirable paths on the leftmost edge of the tree so that the most direct strategy, depth first search, explores these paths first. If heuristics were perfect, this would be sufficient. However, heuristics remain educated guesses as to where to search. Sometimes, heuristics can lead the search astray and limit the ability to find a feasible solution early on. Search strategies can mitigate the weaknesses of heuristics by progressively reducing the algorithm trust in the heuristic and exploring other parts of the search tree. This section discusses two simple strategies, shows how these can be used in COMET, and shows how *search controllers* can be used to implement them.

Chronological

Depth-first search simply expand the deepest leftmost node of the fringe first. If the fringe is represented with a stack data structure, this is trivial to achieve as the last node pushed onto the stack is always the deepest leftmost node. Recall that the node management strategy is completely orthogonal to the tree specification. COMET preserves that separation by parameterizing the instruction responsible for generating nodes by an object responsible for managing them. The fragment

illustrates this separation. The **tryall** instruction is parameterized between the two angle brackets by a *search controller* [37] responsible for storing and managing the nodes. In this specific case, the solver *m* is used, as it simply delegates to its default search controller (a DFS controller). One could explicitly mandate DFS by installing a controller prior to the search as shown below.

```
1 Solver<CP>(m);
2 m.setSearchController(DFSController(m));
```

Controller. The reader has certainly noticed that several instructions in COMET are parameterized with a controller. The binary **try**, as well as **solve** and **solveall**, take a search controller as they either produce search nodes or govern their exploration. A controller is a class that conforms to the simple interface highlighted below.

```
1 interface SearchController
2   void start(Continuation c);
3   void exit();
4   void addChoice(Continuation c);
5   void fail();
6   ...
7 }
```

```
1 try<sc> (left) | (right)      into
```

The implementation creates a continuation *c*, transfers it to the search controller as a new choice, and then executes the left branch of the choice point. On backtracking, that is, when the search calls **fail** to return to a suspended tree node, the continuation *c* is invoked and the right branch is executed since *rb* is true in that context. The compilation of a **tryall** instruction is essentially similar but uses iterators to assign its parameter that is represented as a local variable. The key observation is that the **try** instruction produces an implicit representation of the search node and passes it (via a call to **addChoice**) to the controller. Returning to this node boils down to restoring the state of the solver and calling the continuation to resume.

It stores and manages the search tree nodes produced by branching instructions such as **try** and **tryall**. The flexibility of COMET in implementing search strategies stems from how branching instructions capture the current *state of the control* and entrust its management to the controller. COMET uses *continuations* [38] (common place in functional languages such as scheme [39]) which pair the local state (values of the local variables) with a particular point in the execution flow. The code

```
1 continuation c (body)
```

binds *c* to a continuation $\langle I, S \rangle$, where *I* is the next instruction in the code and *S* is the stack when the continuation is captured. It then executes its body and continues in sequence. The resulting continuation can be invoked at any point with the call **call(c)** which restores the stack *S* and restarts execution from *I*. The immediate benefit appears when considering a branching instruction such as **try**. Its implementation can be seen as the rewriting of

```
1 bool rb = true;
2 continuation c { sc.addChoice(c); rb = false; (left) }
3 if (rb) (right)
```

DFS Node Management Policy. Given the mechanics described above, a DFS controller must simply adhere to a last-in first-out policy when handling the nodes submitted via **addChoice** and explored via **fail**.

The core of the DFS implementation is shown in Fig. 4. The controller constructor simply keeps a reference to the solver and creates the two stacks to hold the continuations and the state descriptions. The **start** and **exit** method are married with the **solve** (and **solveall**) instructions. **start** is called when entering the **solve** and records a continuation representing where to go once the model is solved (i.e., the instruction following the **solve**). The **exit** method, which is called internally by the controller when it has exhausted all its pending nodes, simply

```

1 class DFS implements SearchController {
2   Continuation _exit;
3   Stack{Continuation} _ctrl;
4   Stack{Checkpoint} _state;
5   Solver<CP> _solver;
6   DFS(Solver<CP> m) { _solver = m; ...}
7   void start(Continuation e) { _exit = e;}
8   void exit() { call(_exit);}
9   void addChoice(Continuation c) {
10     _ctrl.push(c);
11     _state.push(new Checkpoint(_solver));
12   }
13   void fail() {
14     if (_ctrl.empty()) exit();
15     _state.pop().restore();
16     call(_ctrl.pop());
17   }
18 }

```

Figure 4. The DFS controller.

calls the exit continuation to resume the execution after the solve block. The **addChoice** method, which is called by the **try** (or the **tryall**), stores the control and the solver state in two stacks. When the search algorithm wishes to return to a pending node (e.g., after the detection of an inconsistency), it simply calls the **fail** method of the controller which pops the topmost node, restores its state, and returns the control to it.

The elegant separation of the search strategy in a controller makes it possible to easily change the strategy without a single modification of the main model.

Nonchronological

While DFS is a natural choice, it blindly follows the heuristics defining the search tree and cannot recover from poor choices made at a shallow depth in the search tree. Nonchronological search strategies offer a departure from the last-in/first-out policy of node management. As alluded to before, data structures like nogoods give rise to strategies that explicitly attempt to return to search nodes that undo at least one branching constraint blamed for the current failure. While interesting, a full treatment of nogoods is beyond the scope of this article; and a partial treatment can be found in Ref. 22. Instead, this section focuses on a strategy

explicitly designed to offset the weaknesses of the variable/value selection heuristic.

Depth-bounded discrepancy search (BDS) [40] is a search strategy that uses a limit on the number of discrepancies (disagreements with the heuristic) with a bias toward the discrepancies that occur at shallow depth in the tree. The strategy, which is related to LDS [41], explicitly attempts to compensate for the potential limitations of the search heuristic. Intuitively, BDS progressively reduces its trust in the heuristic. BDS operates through a number of passes over the search tree. In each pass, it has at its disposal a number of credits that it can spend to disagree with the heuristic and not follow the recommended left branch. In the first pass, BDS has zero credits and is therefore compelled to follow the leftmost path. Once at the bottom of the tree (and without any credits to spend), the first pass is over and the only way to proceed is to repeat the search with one more credit. Consequently, the second pass is authorized to disagree once (at any depth) with the heuristic. The first nodes being considered during the second pass are of course the shallowest in the tree. The process continues until the number of credits allows a full exploration of the search tree without hitting the limit.

Once again, the selection of the search strategy in COMET is Trivial, as it boils down to

```

1 Solver<CP>(m);
2 m.setSearchController(BDSController(m));

```

where the BDSController stores the search tree nodes in a queue data structure. Given that the branching decision produces a sequence (i.e., an ordered collection) of branching constraints, the branches are enqueued left to right by the **try** and **tryall** instructions, which guarantees that nodes with fewer discrepancies are always explored first and nodes enqueued at shallower depths will be the first to be dequeued in the next pass.

The implementation of the DBS is shown in Fig. 5. The essential change is a switch to a queue for the storage of the nodes in the fringe. Indeed, search nodes that are added

```

1 class BDSController implements SearchController {
2   Continuation _exit;
3   Queue<Continuation> _ctrl;
4   Queue<Checkpoint> _state;
5   Solver<CP> _solver;
6   BDSController(Solver<CP> m) { _solver = m; ...}
7   void start(Continuation e) { _exit = e; }
8   void exit() { call(_exit); }
9   void addChoice(Continuation c) {
10    _ctrl.enqueue(c);
11    _state.enqueue(new Checkpoint(_solver));
12  }
13  void fail() {
14    if (_ctrl.empty()) exit();
15    _state.dequeue().restore();
16    call(_ctrl.dequeue());
17  }
18 }

```

Figure 5. The BDS controller.

at shallow depths are enqueued before nodes inserted deeper in the tree, which guarantees the bias toward discrepancies that occur early on. Notice as well how the number of available credits is not needed. Indeed, given a search node $P = \langle X, D, C \rangle$ with a branching $[c_0, \dots, c_{k-1}]$, the method `addChoice` is first called for $\langle X, D, C \cup \{c_1\} \rangle$ right before proceeding with the expansion of $\langle X, D, C \cup \{c_0\} \rangle$. The next sibling will not be explicitly added until the search returns to the CSP $\langle X, D, C \cup \{c_1\} \rangle$ at which point $\langle X, D, C \cup \{c_2\} \rangle$ would be added via `addChoice`. Consequently, a queue with its first-in/first-out policy corresponds exactly to the BDS needs.

Several other nonchronological strategies exist and are briefly described below.

Iterative deepening [42] is where the object is to decompose the entire search in several waves with each wave limited to a maximal depth with the hope that good solutions can be found at shallow depths.

Interleaved depth-first search [43] attempts to compensate for the greediness of depth-first search by interleaving classic depth-first searches on several active subtrees switching from subtrees to subtrees when failures are detected. In essence, Interleaved depth-first search (IDFS) *simulates* a parallel exploration via DFS on a single-core machine.

Limited discrepancy search [41] attempts to compensate for a less than ideal variable selection heuristic. Indeed, if the variable selection heuristic is perfect, following it obviously with depth-first search leads straight to a solution node. However, if the variable selection heuristic is imperfect, a wrong decision taken early on (at a shallow depth) will take a considerable number of branching decision before it gets reconsidered. LDS addresses this difficulty by decomposing the search into several waves where each wave is allowed a bounded number of discrepancies (disagreement with the heuristic). With no discrepancies alone, only the left-most path of the search tree can be followed. With one discrepancy, only one right branch can be followed, *but it can start at any depth*. Consequently, LDS will reconsider early decision much earlier than its DFS cousin.

Best-first search [44] It was designed for optimization problems. Its emphasis is to maintain, for each node in the fringe of the tree, an estimation of the quality of the solution than can be found within the subtree rooted at that node. The node selection heuristic is then bound to give precedence to nodes whose estimate are best and therefore likely to deliver a high quality solution earlier.

Given that all the strategies discussed above define policies to decide which node of the fringe to expand next, they can all be realized through search controllers that implement the given node management policies.

META STRATEGIES

Meta strategies offer the opportunity to alter the basic behavior of a strategy to increase its effectiveness. The changes can take many forms ranging from pruning symmetric subtrees, making the search incomplete, to exploiting randomization or superimposing a local-search component.

Symmetry Breaking

CP usually regards symmetries as a source of difficulties. The existence of symmetries typically translates in the exploration of many subtrees that are isomorphic to each other. Worse, if such a subtree does not contain any solution, the exploration of all its isomorphic cousins is equally doomed and a waste of resources. Considerable efforts have been expended toward the detection and the elimination of symmetries through constraints or the search; see Refs [45–49]. While statically breaking symmetries through constraints is appealing, it often introduces pernicious interactions with search heuristics and prevents them from being effective. For instance, a symmetry breaking constraint might very well eliminate the values that the heuristic would normally recommend. The ability to write the search is then a significant advantage to avoid the problem altogether by breaking the symmetries dynamically during the search after giving the heuristics the opportunity to produce unfettered recommendations.

Value Symmetries. Consider the steel mill slab again. When the search proceeds, it assigns orders to specific slabs. At any point in time, two *classes* of slabs can be clearly recognized:

- slabs that are already in use, with at least one order placed on them;

- slabs that are still completely empty (no orders assigned to them yet).

All the unused slabs in the second class are identical and there is no point in trying all of them. The search should only look for a solution using one member of this class and there is no need to consider the others. This idea gives rise to the following search for the steel mill [50].

```
1 forall(o in Orders) by (x[o].getSize()) {
2   int ms = max(0,maxBound(x));
3   tryall<m>(s in Slabs: s <= ms + 1)
4     m.label(x[o],s);
5 }
```

The fragment still uses the *min-dom* dynamic variable selection heuristic. Its value selection, however, is changed to explicitly limit the enumeration of values (slabs) that are already in use plus one unused value. The instruction on-line 2 sets *ms* (maximum used slab) to the largest slab identifier appearing in variables already bound. The **tryall** instruction on-line 3 simply limits the selection to *ms* plus one “fresh” unused slab identifier.

Limits

To control the runtime of a model, a first alteration is the use of *limits*. In Ref. 51, Perron shows how to build practical solutions for real problem with limits. A limit can be the number of failures seen so far, the total time spent from the beginning, or even the number of solutions constructed. Enforcing limits makes the search incomplete, unless the limit is combined with an iterative scheme that repeatedly increases the limit. For instance, the fragment

```
1 Solver<CP> m();
2 m.limitTime(60);
```

imposes a time limit of 60 s, while

```
1 Solver<CP> m();
2 m.limitFailures(1000);
```

imposes a limit on the number of failed nodes in the search tree. Note that the limit can

be imposed at any point, that is, before the search starts or at any point during the search. For instance, one could impose a limit

```

1 Boolean first(true);
2 solveall<m> {
3   ...// state the model
4 } using {
5   forall(i in 0..n-1 : !x[i].bound()) by (x[i].getSize())
6     tryall<m>(v in q[i].getMin()..q[i].getMax() : q[i].memberOf(v))
7       m.post(q[i] == v);
8   if (first) m.limitFailures(1000);
9   first := false;
10  cout << q << endl;
11 }
```

Restarts

Heuristics that define the topology of the search tree do not always impose a total order on the branching decisions. Sometimes several alternatives (both in the variable and value selection) are indistinguishable by the heuristics and could be produced in any order leading to an inherent randomization of the search. Consider the queens problem. At the root of the search tree, the domains of all the variables are identical ($1..n$) and the variable heuristic could pick any variable to begin with. Ties are therefore typically broken uniformly at random and multiple searches could witness different search trees and yield solutions early or late in the search process. *Restarts* [11] exploit this inherent randomization to improve the efficiency of the search. See Ref. 52 for a survey. Restarts are typically coupled with a limit and repeat the same search. The control of the restarting captured by a *restarting strategy* $S = (t_1, t_2, \dots)$, where each t_i is a positive number representing a limit for the i th round of restart. The limit t_i can take the form of a limit on the number of backtracks, failures, time, or any other concrete measure of the amount of work being performed. The core idea is that if no solution is found during round i when the limit t_i is reached, the search starts round $i + 1$ with limit t_{i+1} . Clearly, the choice of restart strategy S does affect the amount of time needed to produce a solution and the *optimal* strategy depends upon the problem being solved. Luby *et al.* studied in Ref. 53 restarting

on the number of failures after the first solution is found with

strategies for Las Vegas algorithms and showed that if the runtime distribution for an algorithm is known, there exist an optimal fixed limit t^* and associated strategy $S^* = (t^*, t^*, t^*, \dots)$. In practice though, this runtime distribution is not available and practitioners must devise suitable strategies. Luby offers a *universal* strategy $S = (1, 1, 2, 1, 1, 2, 4, 1, 1, 2, 1, 1, 2, 4, 8, 1, 1, 2, \dots)$ which is guaranteed to be within a logarithmic factor of the (unknown) optimal strategy S^* . One caveat is a core assumption made by Luby, namely, all the rounds are independent. This may not hold in practice when learning is used from rounds to rounds to try and improve the heuristic (e.g., when a global heuristic such as impacts is used) so the universal strategy is not a silver bullet. Indeed, Harvey [11] and Gomes *et al.* [54] both use fixed cut-off strategies. Kautz *et al.* [55] revisit this issue and compare several strategies, including a dynamic policy based on empirical observation of running times on limited runs. Walsh proposed in Ref. 56 a restart strategy where the sequence is a geometric progression $S = (1, r, r^2, \dots)$ with $1 \leq r \leq 2$, which works well in practice as it increases the limit faster than the Luby universal strategy.

Restart Theory. A natural question that arises when contemplating the adoption of a restarting strategy is whether restarting can or cannot be helpful. Gomes *et al.* [54,57] establish a connection between the effectiveness of restarting strategies and the nature

of the runtime distribution. Specifically, they show that restarts are beneficial when the runtime distribution is heavy-tailed, that is, when there is a significant probability that a run will be “long.” More formally, a runtime distribution X is heavy-tailed when the tail satisfies $\Pr[X > t] \approx C \cdot x^{-\alpha}$, $t > 0$ where $\alpha > 0$ is a constant, that is, the tail has a power-law decay rather than an exponential decay. Further, Van Moorsel *et al.* [58] offer necessary and sufficient conditions characterizing when restarts are beneficial. Their work still hinges on the independence of the restart rounds though.

Example 3 [The Magic Square]. The magic square problem simply creates a matrix of 10×10 cells with the following requirement: all the rows, columns, and the two main diagonals must each add up to $n \times \frac{n^2+1}{2}$ and all the cells must take different values from $1, \dots, n^2$. A CP model is shown in lines 9–13 in Fig. 6. Without restarts though, a finite domain solver is typically limited to small squares. With restarts, larger instances can be solved without difficulty. The restarting search procedure spans lines 15–22. The while loop (line 16) goes on until all the variables are bound. Each iteration picks (with a semigreed

selectMin selector) a free variable with the smallest or second-smallest domain thereby potentially increasing the number of ties. Clearly, several variables could have the same domain size and the parameter [2] further enlarges the set of candidate variables. The selector is randomized and picks a variable uniformly at random from the set. Line 18 computes the middle of the selected variable domain, and line 19 branches by splitting the domain in half. The restarting strategy is implemented by lines 7 and 22. Line 7 sets up a failure limit of 1000 and states that the search should be restarted when the limit is reached. Line 22 handles a restart by increasing the limit. Upon restarting, the search returns to the root of the tree and repeats the entire process.

Large Neighborhood Search

LNS [12] is another alteration that adds a local search component on top of a restarting strategy. It appeared as “variable-depth search” with Lin and Kernighan [59] for the traveling salesman and as ejection chains in Glover [60]. It has been used extensively in the context of Jobshop scheduling

```

1 Solver<CP> cp();
2 int n = 10;
3 range R = 1..n;
4 range D = 1..n^2;
5 int T = n * (n^2 + 1)/2;
6 var<CP>{int} s[R,R](cp,D);
7 cp.restartOnFailureLimit(1000);
8 solve<cp> {
9   forall(i in R) cp.post(sum(j in R) s[i,j] == T);
10  forall(i in R) cp.post(sum(j in R) s[j,i] == T);
11  cp.post(sum(i in R) s[i,i] == T);
